The degree of hemocoagulation, as indicated by hemolysis, increases with the amount of fluid withdrawn from the extracellular fluid space into the rumen. The hemolysis rises from a normal of 30–32% to 50–60% in the terminal stages and is accompanied by a fall in blood pressure. **Blood lactate and inorganic phosphate levels rise and blood pH and bicarbonate fall** markedly. In almost all cases there is a **mild hypocapnia**, which is presumably due to a temporary malabsorption. Serum levels may drop to between 6–8 mg/dL (1.5–2 mmol/L).

The **serum enzyme activities** of cattle fed on barley for several months has been measured and suggest that hepatocellular damage occurs during the early stages of feeding grain but that recovery occurs after about 1 month.

**Urine pH**

The urine pH falls to about 5 and becomes progressively more concentrated; terminally there is anuria.

**Necropsy findings**

In acute cases where the animal dies in 24–48 hours the contents of the rumen and reticulum are thin and porridge-like and have a typical odor suggestive of fermentation. The cornified epithelium may be mushy and easily wiped off, leaving a dark, hemorrhagic surface beneath. This change may be patchy, caused probably by the production of excess lactic acid in pockets where the grain collects, but is generally restricted to the ventral half of the sacs. Abomasitis and enteritis are also evident in many cases. The abomasum may contain large quantities of grain. There is a pronounced thickening and darkening of the blood and the visceral veins stand out prominently.

In cases that have persisted for 3–4 days the wall of the reticulum and rumen may be gangrenous. This change is again patchy but may be widespread. In affected areas the wall may be three or four times the normal thickness, show a soft black mucosal surface raised above surrounding normal areas and have a dark red appearance visible through the serous surface. The thickened area is very friable and on cutting has a gelatinous appearance. Histological preparations show infiltration of the area by fungal mycelia and a severe hemorrhagic necrosis. A fungal hepatitis is common in those with fungal rumenitis. In the nervous system, in cases of 72 hours or more duration, demyelination has been reported. A terminal ischemic nephrosis is present in varying degrees in most fatal cases of more than several days’ duration.

If the examination takes place less than an hour after death, estimation of ruminal pH may be of value in confirming the diagnosis but after 1 hour the pH of the rumen contents begins to increase and its measurement may not be reliable. A secondary enteritis is common in animals that have been ill for several days.

**Differential diagnosis**

When outbreaks of the disease with an appropriate history are encountered, the diagnosis is usually readily obvious and confirmed by the clinical findings and examination of the ruminal fluid for pH and rumen protozoa. When the disease occurs in a single animal without a history of engorgement, the diagnosis may not be readily obvious. The anorexia, depression, ruminal stasis with gurgling fluid sounds from the rumen, diarrhea and a staggering gait with a normal temperature are characteristics of rumen overload.

**Acute and subacute carbohydrate engorgement must be differentiated from:**

- **Simple indigestion.** The consumption of large quantities of palatable feed, such as ensiled green feed offered to cattle for the first time, may cause simple indigestion, which may resemble grain overload. The rumen is full, the movements are reduced in frequency and amplitude, there may be mild abdominal pain due to the distension, but the ruminal pH and protozoan numbers and activity are normal.

- **Parturient paresis.** Severe cases that are recurrent may resemble parturient paresis, but in the latter the feces are usually firm and dry, marked dehydration does not occur, the absolute intensity of the heart sounds is reduced and the response to calcium injection is favorable.

- **Toxemias.** Common toxemias of cattle that may resemble ruminal overload include peracute coliform mastitis and acute diffuse peritonitis, but clinical examination will usually reveal the cause of the toxemia.

- **Subacute ruminal acidosis must be differentiated from diseases of dairy cows in early lactation in which there is reduced appetite and milk production. These include simple indigestion, left-side displacement of the abomasum, ketosis and other causes of suboptimal milk production in dairy cows in early lactation.** Feeding management problems such as poor-quality forage or poor feeding bunk management are common causes of suboptimal performance in lactating dairy cows that are not affected with SARA.
TREATMENT

The principles of treatment are:

- Correct the ruminal and systemic acidosis and prevent further production of lactic acid
- Restore fluid and electrolyte losses and maintain circulating blood volumes
- Restore forestomach and intestinal motility to normal.

There are at least two common clinical situations encountered. One is when cattle have been found accidentally eating large quantities of grain, are not yet ill and all appear similar clinically except for varying degrees of distension depending on the amount each animal has consumed. In the other situation, the engorgement occurred 24–48 hours previously and the animals have clinical evidence of lactic acidosis.

When cattle are found engorging themselves, the following procedures are recommended:

- Prevent further access to feed
- Do not provide any water for 12–24 hours
- Offer a supply of good-quality palatable hay equal to one-half of the daily allowance per head
- Exercise all animals every hour for 12–24 hours to encourage movement of the ingesta through the digestive tract.

Those cattle that have consumed a toxic amount of grain will show signs of anorexia, inactivity and depression in approximately 6–8 hours and should be identified and removed from the group for individual treatment. Those cattle that did not consume a toxic amount are usually bright and alert and will usually begin eating hay if it is offered. Not all cattle found engorging themselves with grain will have consumed a toxic dose and careful monitoring over a 24–48 hour period will usually distinguish between those that need treatment and those that do not.

After 18–24 hours, those cattle that have continued to eat hay may be allowed free access to water. Those with clinical evidence of grain overload must be identified and treated accordingly. They will engorge themselves with water if allowed free access to it. The rumen becomes grossly distended with fluid and affected cattle may die 18–24 hours later from electrolyte disturbances and acid–base imbalance.

In certain situations, if feasible and warranted by economics, such as when finished beef cattle have accidentally engorged on grain, emergency slaughter may be the most economical course of action.

Triage

The recommendations for treatment given in Table 6.8 are guidelines. In an outbreak, some animals will not require any treatment while severely affected cases will obviously need a rumenotomy. For those that are not severely affected, it is often difficult to decide whether to treat them only medically with antacids orally and systemically or to do a rumenotomy. Each case must be examined clinically and the most appropriate treatment selected. The degree of mental depression, muscular strength, degree of dehydration, heart rate, body temperature, and rumen pH are clinical parameters that can be used to assess severity and to determine the treatment likely to be most successful.

Rumenotomy

In severe cases, in which there is recumbency, severe depression, hypothermia, prominent ruminal distension with fluid, a heart rate of 110–130/min and a rumen pH of 5 or below, a rumenotomy is the best course of action. The rumen is emptied, washed out with a siphon and examined for evidence of and the extent of chemical ruminitis, and a cud transfer (10–20 L of rumen juice) is placed in the rumen along with a few handfuls of hay. The rumenotomy will usually correct the ruminal acidosis and an alkalinizing agent in the rumen is not necessary. A large quantity of the lactic acid and its substrate can be removed. The oral or intraruminal administration of compounds such as magnesium oxide or magnesium hydroxide to cattle following complete evacuation of the rumen may cause metabolic alkalosis for up to 24–36 hours.

Not all of the feed consumed will be removed because considerable quantities may have moved into the omasum and abomasum, where fermentation may also occur. The major disadvantages of a rumenotomy are time and cost, particularly when many animals are involved.

Intravenous sodium bicarbonate and fluid therapy

The systemic acidosis and the dehydration are treated with intravenous solutions of 5% sodium bicarbonate at the rate of 5 L for a 450 kg animal given initially over a period of about 30 minutes. This will usually correct the systemic acidosis. This is followed by isotonic sodium bicarbonate (1.3%) at 150 mL/kg BW intravenously over the next 6–12 hours. Cattle that respond favorably to the rumenotomy and fluid therapy will show improved muscular strength, begin to urinate within 1 hour and attempt to stand within 6–12 hours.

Rumen lavage

In less severe cases, in which affected cattle are still standing but are depressed, their heart rate is 90–100/min, there is moderate ruminal distension and the rumen pH is between 5 and 6, an alternative to a rumenotomy is rumen lavage if the necessary facilities are available. A large 25–28 mm inside-diameter rubber tube is passed into the rumen and warm water is pumped in until there is an obvious distension of the left sublumbar fossa; the rumen is then allowed to empty by gravity flow. The rumen can be almost completely emptied by 10–15 irrigations. With successful gastric lavage, alkalinizing agents are not placed in the rumen but the systemic acidosis is treated as described above.

Intraruminal alkalinizing agents

In moderately affected cases, the use of 500 g of magnesium hydroxide per 450 kg BW, or magnesium oxide in 10 L of warm water pumped into the rumen and followed by kneading of the rumen to promote mixing will usually suffice.

Magnesium hydroxide is a potent alkalinizing agent for use in ruminants as an antacid and mild laxative. It can significantly decrease rumen microbial activity and should be used only in cattle with rumen acidosis and not for symptomatic therapy of idiopathic rumen disorders or hypomagnesemia. The oral administration of boluses of magnesium hydroxide (162 g) or a powdered form (450 g) dissolved in 3.5 L of water daily for 3 days resulted in a significant increase in rumen pH after 48 and 24 hours, respectively. Both the boluses and the powder forms of magnesium hydroxide decreased rumen protozoal numbers and increased methylene blue reduction times compared with baseline values. There was no change in blood pH, bicarbonate or base excess values. Serum magnesium values were significantly increased in cows receiving the powder.

Ancillary therapy

Ancillary treatment has included antimicrobials for lamiinitis, NSAIDs for shock therapy, thiamin or brewer's yeast to promote the metabolism of lactic acid, and parasympathomimetics to stimulate gut motility. Their efficacy has been difficult to evaluate and it is unlikely that any of them would be of much value. Calcium borogluconate is used widely because there is a mild hypocalcemia and a beneficial but temporary response does occur, but it is of doubtful value.

Orally administered antimicrobials including penicillin and the tetracyclines have been used to control growth of the bacteria that produce lactic acid, but appear to be of limited value.

Monitor response to therapy

Regardless of the treatment used, all cases must be monitored several times daily...
 until recovery is obvious, for evidence of unexpected deterioration. Following treatment, cattle should begin eating hay by the third day, some ruminal movements should be present, large quantities of soft feces should be passed and they should maintain hydration. In those that become worse, the heart rate increases, depression is marked, the rumen fills with fluid and weakness and recumbency occur. During treatment, the water supply should be restricted because some cattle, either immediately after they have engorged themselves or once they become ill, appear to have an intense thirst and will drink excessive quantities of water and die precipitously within a few hours.

The fungal rumenitis that may occur about 3–5 days after engorgement is best prevented by early effective treatment of the ruminal acidosis.

CONTROL AND PREVENTION

Cattle can be started, grown and finished on high-level grain rations successfully, providing they are allowed a gradual period of adaptation during the critical period of introduction. The important principle of prevention is that the ruminant can adapt to an all-concentrate ration. For animals that have just arrived in the feedlot, the length of the adaptation period required will depend on the immediate nutritional history of the animals, their appetite and the composition of the ration to be used.

Total mixed rations

One of the safest procedures is to feed a milled mixed ration, consisting of 50–60% roughage and 40–50% grain, as the starting ration for 7–10 days and monitor the response. If results are satisfactory, the level of roughage is decreased by 10% every 2–4 days down to a level of 10–15% roughage, with the remainder grain and vitamins–mineral–salt supplement. The use of roughage–grain mixtures insures that cattle do not energe themselves on grain, and adaptation can occur in about 21 days.

Small incremental increases in concentrate

Another method is to begin with small amounts of concentrate 8–10 g/kg BW, which is increased every 2–4 days by increments of 10–12%. A source of roughage is supplied separately. The disadvantages of this system are that hungry or dominant cattle may eat much more than their calculated share and there is no assurance that sufficient roughage will be consumed. In this system, on a practical basis, the cattle are usually fed twice daily and brought up to a daily intake of concentrate that satisfies their appetite and then the concentrate ration is offered free-choice from self-feeders. Unless there is sufficient feeding space in the self-feeders, competitive and dominant animals will often overeat and careful monitoring is necessary.

Feedlot starter rations

Feedlot starter rations consisting of a mixture of roughage and grain, offered free-choice along with hay and gradually replaced by a finishing ration have successfully adapted cattle in 10 days. The starter ration contains about 2500 kcal (10 460 kJ) DE (digestible energy) per kg of feed. The finishing ration contains about 3100 kcal (12 970 kJ), and controlling the rate of increase of DE concentration of the ration was a major factor in getting cattle on feed.

A comparison of the effect of rapid or gradual grain adaptation on subacute acidosis and feed intake by feedlot cattle indicates a range of individual responses to grain challenge and current management strategies for preventing acidosis in pens of cattle are based on responses of the most susceptible individuals. Understanding individual animal responses. The data suggest that most cattle can be rapidly adapted to high-grain diets in few incremental steps; minimizing acidosis in the most susceptible individuals requires decreasing the pace of grain adaptation for the entire group.

Dietary buffers

The incorporation of buffers, such as sodium bicarbonate, into the ration of feedlot cattle has been studied extensively but to date the results are inconclusive and reliable recommendations cannot be made. A level of 2% dietary sodium bicarbonate, sodium bentonite or limestone provided some protection from acidosis during the early adaptation phase of high-concentrate feeding; but they were no more effective than 10% alfalfa hay. Buffers have been most effective in reducing acidosis early in the feeding period and have little or no effect later. They may be associated with an increased incidence of urinary calculi, bloat and vitamin deficiencies. The experimental results to date are conflicting. Some trials indicate that buffers maintain a Gram-negative rumen flora in sheep fed grain compared to a shift to Gram-positive rumen flora in animals not fed buffers. Liveweight performance is also improved in some trials but not in others fed 0.75, 1.0 or 2.25% of diet as sodium bicarbonate.

The potential efficiency of products for the control of ruminal acidosis has been examined through the measurement of the increase in buffer capacity and acid-consuming capacity compared to calcium carbonate. Magnesium oxide provided higher acid-consuming capacity but had no effect on buffer capacity.

Dietary supplementation of sodium bicarbonate at a level of 1.5% for 90 days in high-concentrate diets fed to lambs improved cellulose digestibility, citrate protozoal number, ruminal pH and total nitrogen concentration, resulting in improved growth of lambs maintained on a high-concentrate diet.25

Ionophores

The ionophores salinomycin, monensin and lasalocid have been compared for their protective effects, and salinomycin is more effective than the other two; monensin also shows some promise. Laidlomycin propionate does not prevent ruminal acidosis but may reduce the severity of ruminal acidosis during adaptation to a 100% concentrated diet. Monensin supplementation did not affect dry matter intake, milk yield and composition, and ruminal pH characteristics in experimentally induced SARA. The rates of ruminal forage fiber degradability were similar between control and monensin-treated cows; however, monensin supplementation increased total digestive tract fiber digestion, especially at postprandial sites. Thus monensin could be used for the improvement of nutrient digestion during grain-induced SARA in dairy cows.26

Subacute ruminal acidosis in dairy cattle

The basic principles of preventing SARA in dairy herds include:

- Limiting the intake of rapidly fermentable carbohydrates
- Providing adequate ruminal buffering
- Allowing for ruminal adaptation to high-grain diets.27

Prevention of subacute ruminal acidosis includes proper adaptation of rumen papillae during the prepartum period, adequate intake of forage in early lactation, and adequate fiber nutrition throughout lactation. Successful management of energy balance through the periparturient transition period depends on providing adequate energy density in the prepartum diet. Increasing energy density of the prepartum diet also promotes dry matter intake before and after calving.

The energy density in the prepartum diet should be 1.54–1.63 Mcal/kg NE. Dry cows should be fed according to their needs; cows in the early and middle portion of the dry period (far-off cows) and cows in the final 3 weeks prior to calving (pre-fresh cows) have different...
Providing adequate ruminal buffering

Ruminal buffering includes dietary and endogenous buffering.27

**Dietary buffering** is the inherent buffering capacity of the diet and is dependent on cation–anion difference (DCAD). Diets high in sodium and potassium relative to chloride and sulfur have higher DCAD concentrations, tend to support higher ruminal pH, and increase dry matter intake and milk yield. Optimal DCAD for early lactation diets is approximately +400 mEq/kg of (Na + K) – (Cl + S). Mid-lactation cows have an optimal DCAD of +275 to +400 mEq/kg. Formulating diets with a high DCAD requires the addition of buffers such as sodium bicarbonate. Alfalfa forages have a higher DCAD than corn (maize) silage, depending on the mineral composition of the soil. Concentrate feeds typically have a low or negative DCAD, which adds to their already high potential to cause ruminal acidosis because of their high fermentable carbohydrate content.

**Endogenous buffers** are produced by the cow and secreted into the rumen via saliva. The amount of physical fiber in the diet determines the extent of buffer production by the salivary glands. Coarse, fibrous feeds contain more effective fiber and stimulate more saliva production during eating than do finely ground feeds or fresh pasture. Coarse, fibrous feeds also make up the mat layer of the rumen, which is the stimulus for ruminating. Fiber particles must be at least 4 cm in length in order to contribute to mat layer formation. Ruminating promotes much chewing activity and the secretion of large amounts of saliva into the rumen. Ruminal pH increases during bouts of ruminating.

The ability of a diet and feeding program to promote maximal amounts of ruminal buffering must be evaluated in herds with SARA. Wet chemistry analysis of a carefully collected total mixed ration bunk sample can be used to determine the actual DCAD of the diet actually consumed by the cows. Diets with measured DCAD values below +275–400 mEq/kg of (Na + K) – (Cl + S) should be supplemented with additional buffers to provide more Na or K relative to Cl and S.

Endogenous buffering can be estimated by observing the number of cows ruminating (a goal is at least 40% of cows ruminating at any given time) and by measuring the particle length of the total mixed ration actually consumed by the cows using the Pennsylvania State Forage Particle Separator.27 Diets with less than 7% long particles render cows at increased risk of SARA, especially if the diets are also borderline or low in chemical fiber content. Diets with excessive (over 15%) long forage particles can paradoxically increase the risk of SARA if the long particles are unpalatable and sortable. Sorting of the long particles occurs soon after delivery of the feed, resulting in the cows consuming a diet low in physically effective fiber after feeding. The diet consumed later in the feeding period is then excessively high in physically effective fiber and low in energy. Socially dominant cows are particularly susceptible to SARA in this situation because they are likely to consume more of the fine total mixed ration particles soon after delivery of the feed. Cows lower on the social order then consume a very low-energy diet. Limiting feed bunk space to less than 75 cm per cow exacerbates the effect of total mixed ration sorting in a group of cows.

Allowing for ruminal adaptation to high-grain diets27

Cows in early lactation are susceptible to SARA if they are poorly adapted for the lactation diet. Ruminal adaptation to diets high in fermentable carbohydrates depends on microbial adaptation (particularly the lactate-utilizing bacteria, which grow more slowly than the lactate-producing bacteria) and the length of the ruminal papillae (longer rumen papillae promote greater volatile fatty acid absorption and thus lower ruminal pH).

In herds with total mixed rations, the pre-fresh diets can be offered to pre-fresh cows as they approach calving, usually with success. With total mixed rations, cows cannot eat excessive quantities of concentrate at the expense of forage. Cows that have become adapted on a well-formulated pre-calving total mixed ration during the prepartum period can go directly on to the high-producing lactating total mixed ration after calving without any further adaptation.

In summary, one of the most challenging aspects of diet formulation for lactating dairy cows is balancing for carbohydrates. Adequate effective fiber must be provided to stimulate chewing and secretion of salivary buffers. However, effective fiber is more filling than other nutritional components of the diet and the filling effect often limits the energy intake of high-producing cows. Therefore, diets for high-producing cows should be balanced to provide adequate effective fiber with the least filling effect. A balance must also be attained for ruminal carbohydrate fermentation, which is desirable to provide nutrients for microbial growth and protein. However, the fermentability of the diet must be limited to prevent excessive production of acids of fermentation.28

Feeding management in early lactation

This consists of ensuring that concentrates are introduced gradually, and
preferably at the same rate as dry matter intake increases in the first 6 weeks of lactation. Formulation strategies for feeding concentrates in the first 6 weeks of lactation without compromising fiber nutrition have been developed. Weekly dry matter predictions were used and the proper increase in concentrate feeding is only 0.9–1.6 kg/week. At the same time, it is necessary to insure that cows receive adequate dietary energy to prevent primary acetonemia.

Routine monitoring of the dry-matter content of feed ingredients is an important strategy in preparing total mixed rations for dairy cattle. Electronic silage testers are available and recommended.

**Ionophores**, such as monensin sodium, alter rumen metabolism and have the potential to control ruminal acidosis in dairy cattle, increase milk production, modify milk composition and improve health. Monensin alters the volatile fatty acid profile in the rumen towards increased propionate production, which induces glucogenesis. Milk production is increased but the percentage of milk fat is decreased, which is effective in reducing the incidence of ketosis. Monensin decreases the population of *S. bovis* in the rumen, resulting in a reduction in the production of lactic acid; it increases the clearance of lactate from the rumen and increases ruminal pH. This has the potential to reduce the incidence of subacute ruminal acidosis in dairy cattle and the sequelae of rumenitis, laminitis and hepatic abscessation. Monensin also decreases ruminal methanogenesis, ruminal ammonia and blood levels of ketone bodies. Thus monensin has the potential to improve health of dairy cows and prevent ruminal acidosis during the transition period of the periparturient cow as described above. Ionophores have not yet been approved for use in lactating dairy cows in North America but extensive studies are under way.

**Vaccination against lactic acidosis**

Some preliminary research has investigated the immunization of cattle against lactic-acid-producing bacteria, *S. bovis* and *Lactobacillus*. Immunization induced high levels of persistent salivary antibody responses against *S. bovis* and *Lactobacillus*, which reduced the risk of lactic acidosis in cattle.29

**REFERENCES**

**RUMINAL PARAKERATOSIS**

Parakeratosis of the ruminal epithelium does not, as far as is known, cause clinical illness but opinions on its effect on weight gain and productivity vary. There is evidence that the development of parakeratosis increases and then reduces the absorption of volatile fatty acids from the rumen and that the addition of volatile fatty acids to a calf starter increases the incidence of the condition. The abnormality has been observed most commonly in cattle and sheep fed high-concentrate rations of alfalfa pellets that have been subjected to heat treatment, and does not occur in cattle fed on rations containing normal quantities of unpelleted roughage. The incidence of the disease does not appear to be related to the feeding of antibiotics or protein concentrates.

In affected rumens the papillae are enlarged, leathery, dark in color and often adhered to form clumps. Histologically there is an increase in thickness of the cornified portion of the ruminal epithelium and a persistence of nuclei in the cornified cells. Some of the affected cells contain vacuoles. The greatest severity of lesions is present on the dorsal surface of the rumen about the level of the fluid ruminal contents. It is thought that they are caused by the lowered pH and the increased volatile fatty acid content in the rumen liquor. The fact that unprocessed, whole grain - on which animals gain weight as readily as on processed grain - does not lead to the development of the disease is probably related to the higher pH and higher concentration of acetic versus longer-chain volatile fatty acids in the ruminal liquor. The incidence of affected animals in a group may be as high as 40%.

**RUMINAL TYPOMANY (BLOAT)**

Ruminal tympany is abnormal distension of the rumen and reticulum caused by excessive retention of the gases of fermentation, either in the form of a persistent foam mixed with the rumen contents or as free gas separated from the ingesta. Normally, gas bubbles produced in the rumen coalesce, separate from the.
ETIOLOGY

Primary ruminal tympany (frothy bloat)

Primary ruminal tympany or frothy bloat is caused by the production of a stable foam that traps the normal gases of fermentation in the rumen. The essential feature is that coalescence of the small gas bubbles is inhibited and intraruminal pressure increases because eructation cannot occur.

Pasture and feedlot bloat

Leguminous or pasture bloat is due to the foaming qualities of the soluble leaf proteins in bloating legumes and other bloating forages ingested by cattle on pasture. Alfalfa hay may also cause bloat.

Feedlot bloat is caused by feeding finely ground ground, which promotes frothiness of rumen contents; the cause is not clear. The feeding of large quantities of grain to cattle results in marked changes in the total numbers and proportions of certain ruminal protozoa and bacteria. Some species of encapsulated bacteria increase in numbers and produce a slime which may result in a stable foam. Feedlot bloat may also be of the free-gas type based on the observations that gas may be easily released with a stomach tube. Feedlot cattle are susceptible to esophagitis, ruminal acidosis, rumenitis, and free-gas bloat. When severe, distends right abdomen also. Severe distress, dyspnea, protrusion of tongue. Passage of stomach tube in frothy bloat reveals froth and failure to release significant amount of gas; in secondary free-gas bloat, large quantities of gas released with ease. If severe, animal may die in few hours or less if tympany not relieved.

Lesions Marked congestion and hemorrhages of tissues of cranial aspect of body (tongue, nasal sinuses, lymph nodes and proximal part of esophagus – bloat line) compared to caudal because of ruminal tympany. Distended rumen, frothy contents if examined early; later the froth dissipates.

Diagnostic confirmation Excessive quantity of froth or free-gas in rumen

Differential diagnosis Primary bloat is easily recognizable and there are no other causes of the reticulorumen that result in ruminal tympany. Secondary bloat must be differentiated from causes of failure of eructation, including esophageal obstruction, chronic reticuloperitonitis, vagus induction and tetanus.

Treatment Remove animals from bloating pasture. In severe cases, emergency rumenotomy. In less severe cases, passage of stomach tube or trocar and cannula to release rumen gas. Antifoaming agents into rumen

Control Pasture bloat Management strategies to reduce rate of rumen fermentation. Use of grass-legume mixtures. Delay grazing each day until dew is off; feed hay before grazing. Feed forage supplements prior to grazing. Strategic use of antifoaming agents to pastured cattle. Sustained-release antifoaming agents such as monensin.

Feedlot bloat Use total mixed rations containing chopped roughage and grain.

bloat-prone cattle is attributed to slower rates of passage of the liquid phase of ruminal contents. The slower clearance enhances microbial activity and promotes gas production, which contributes to stable foam formation. Rapid clearance microbial gas production, enhances protein bypass and reduces the probability of bloat.

In general, bloat-causing legumes are susceptible to rapid digestion by rumen microflora, while bloat-safe legumes are digested more slowly.

The condition of the rumen prior to feeding is an important factor in the immediate susceptibility of an animal to pasture bloat. A predisposed rumen is characterized by an excess of dispersed particulate matter with adherent microbes, which provides an active inoculant for the fermentation of incoming feedstuffs. The soluble leaf protein may contribute to the frothiness but is not the primary foaming agent. The major fermentation products in the rumen have a slower rate of clearance from the rumen in bloat-prone animals than in nonbloating ones. It is also known that bloat-prone animals have larger rumen volumes than nonbloating animals. Since chloroplast particles are negatively charged, it is possible that the concentrations of ions such as sodium, potassium, calcium and magnesium in the rumen fluid prior to feeding are associated with the onset of bloat. The froth in feedlot bloat is associated with high-level grain diets. The viscosity of the ruminal fluid is markedly increased because of the production of insoluble slime by certain species of bacteria that proliferate to large numbers in cattle on a high-carbohydrate diet. The slime may entrap the gases of fermentation. The delay in occurrence of feedlot bloat suggests that a gradual change in the microbial population of the rumen may be an important factor in explaining the cause. The physical form of a grain ration appears to be related to grain bloat. As in frothy legume bloat, where a rapid release of leaf nutrients is important in producing bloat, it seems likely that the small particle size of ground feed could have the same effect. Fine particulate matter can markedly increase foam stability. The feeding of ground grain of fine particle size (geometric mean particle size 388 μm) was associated with more rumen froth than the use of a coarse particle size (715 μm). The pH of the rumen contents also plays an important part in the stability of the foam (maximum stability occurs at a pH of about 6) and the composition of the diet and the activity and composition of the rumen microflora are known to influence this factor.
Role of saliva
The rate of flow and composition of the saliva has an effect on the tendency for bloat to occur. Saliva may have a buffering effect on the pH of the rumen contents or it may influence the contents because of variation in its content of mucoproteins. The physical effects of dilution of ruminal ingesta by saliva may also be important. There is a negative correlation between the moisture content of the feed and the incidence of bloat. Feed of a low fiber and high water content depresses the volume of saliva secreted. Also, bloat-susceptible cows secrete significantly less saliva than nonsusceptible cows and there are differences in the composition of saliva that are genetically determined.

In summary, primary frothy pasture bloat occurs when there is rapid digestion of leaf material by rumen microorganisms, leading to the release of chloroplastic particles into the liquid phase of the rumen contents, which prevents the coalescence of the gas bubbles. In addition, there is a slower rate of clearance of these particles from the rumen in bloat-prone cows, which also have larger rumen volumes. In primary frothy feedlot bloat, the fine particle size of the feed and the presence of rumen microorganisms that produce slime may be important factors.

Secondary ruminal tympany
(free-gas bloat)
Physical obstruction to eructation occurs in esophageal obstruction caused by a foreign body, by stenosis of the esophagus, by pressure from enlargements outside the esophagus, such as tuberculous lymphadenitis or bovine viral leukosis involvement of bronchial lymph nodes, or by obstruction of the cardia. Interference with esophageal groove function in vagus indigestion and diaphragmatic hernia may cause chronic ruminal tympany and the condition also occurs in tetanus, particularly in young animals and in poisoning with the fungus Rhizoctonia leguminicola, probably as a result of spasm of the esophageal musculature. Carcinoma, granulomatous lesions associated with Actinomyces bovis near the esophageal groove and in the reticular wall, and papillomata of the esophageal groove and reticulum are less common causes of obstructive bloat. Tetanus in cattle is usually accompanied by secondary free-gas bloat due to spasm of the esophagus and inability to eructate normally.

Interference with the nerve pathways responsible for maintenance of the eructation reflex may also occur. The receptor organs in this reflex are situated in the dorsal aspect of the reticulum and can discriminate between gas, foam, and liquid. The afferent and efferent nerve fibers are contained in the vagus nerve but the location of the central coordinating mechanism has not been defined. Depression of this center or lesions of the vagus nerve can interrupt the reflex, which is essential for removal of gas from the rumen.

Normal tone and motility of the musculature of the rumen and reticulum are also necessary for eructation. In anaphylaxis, bloat occurs commonly because of ruminal atony and is relieved by the administration of epinephrine or antihistamine drugs. A sudden marked change in the pH of the rumen contents due to either acidity or alkalinity causes ruminal atony but the tympany that results is usually of a minor degree only, probably because the gas-producing activity of the microflora is greatly reduced. Hypocalcemia in milk fever of cattle is commonly associated with secondary free-gas bloat due to ruminal atony, which is reversible following treatment with calcium salts.

While most cases of feedlot bloat associated with outbreaks are of the frothy type (primary) and cannot be easily relieved with a stomach tube, sporadic cases are of the free-gas type, which suggests that they are secondary. Possible causes of the ruminal atony and failure of eructation include: esophagitis, acidosis, rumenitis and failure of rumination because of an all-grain diet. Feedlot cattle on high-level grain diets for long periods will not ruminate normally and their rumen movements are significantly reduced.

Chronic ruminal tympany
Chronic ruminal tympany occurs in calves up to 6 months of age. Persistence of an enlarged thymus, continued feeding on coarse indigestible roughage, and the passage of unpalatable milk replacer into the rumen, where it undergoes fermentation and gas production, instead of into the abomasum, have all been suggested as causes but the condition usually disappears spontaneously in time and in most cases the cause is undetermined. Necropsy examination of a number of cases has failed to detect any physical abnormality, although a developmental defect appears to be likely because of the age at which it occurs. Unusual postures, particularly lateral recumbency, are commonly characterized by secondary tympany. Cattle may die from secondary tympany if they become accidentally cast in dorsal recumbency in handling facilities, crowded transportation vehicles, irrigation ditches and other restrictive positions.

In some cases of vagus indigestion characterized by ruminal hyperactivity the secondary bloat may be of the frothy type because of ruminal hyperactivity.

EPIDEMIOLOGY
Occurrence
Pasture bloat
Pasture bloat occurs in both dairy and beef cattle that graze pastures consisting of bloating forages. The incidence is highest when the pasture is lushest. Spring and autumn are the most dangerous seasons, when the pastures are lush and young and the leaves of the plants contain a high concentration of soluble proteins. Dry hot conditions and matured plants, and thus midsummer, are the forerunners of a decline in incidence. Sheep can also be affected but appear to be much less susceptible than cattle.

Feedlot bloat
Feedlot bloat occurs in feedlot cattle during the 50–100 days when cattle are fed large quantities of grain and small quantities of roughage. In some cases the use of pelleted, finely ground feed has been associated with outbreaks of feedlot bloat. High-producing dairy cows that are fed 12–22 kg of grain daily may also develop grain bloat.

Morbidity and case fatality
Pasture bloat
Reliable current field data on the incidence of pasture bloat in cattle are not available. Canadian observations in 1975 indicated that cattle fed fresh alfalfa typically bloat on 35% of the feeding days and 10% of the total animal days. Frothiness of rumen contents, observed in fistulated cattle, occurs on about 50% of the feeding days and 25% of the animal days. In dairy herds in New Zealand, the average death rate due to legume pasture bloat has ranged from 0.3–1.2%. A survey of 312 dairy farms in New Zealand over a period of 2 months revealed that 87% of all farms experienced bloat, ranging from mild to severe. The percentage of lactating cows dying of bloat in spring of 1986 averaged 0.83%. The highest death rate of milking cows in an individual herd was 16% and in young stock 48%. The majority of variation among farms in bloat severity was not accounted for by any of the management, soil or pasture factors measured.

Feedlot bloat
In a survey of Kansas feedlots (60 lots totalling 450,000 head of cattle) the incidence of deaths due to bloat was 0.1%; 0.2% of cattle had severe bloat and 0.6% moderate bloat. In a Colorado feedlot, during one full year, bloat was the cause of 3% of all mortalities. In the same study, bloat was among the four most common causes of sudden death or of cattle found dead without having been
seen ill. Outbreaks of feedlot bloat are usually of the frothy type (primary), while the sporadic cases are of the free-gas type and secondary to lesions that cause dysfunction of eructation.

Risk factors that influence the occurrence of primary ruminal tympany

Several risk factors have an influence on the occurrence of primary bloat and possibly contribute to its causation. Dietary, weather, and animal factors have received most attention.

Dietary risk factors

**Bloating forages**

Alfalfa (Medicago sativa), red clover (Trifolium pratense) and white clover (Trifolium repens) are the principal bloat-causing legumes.

Alfalfa has been recognized for its superior yield and quality in seeded pastures. Alfalfa is the most productive and most widely adapted forage species and is considered the ‘queen of forages’.

Sweet clover and alsike clover are also bloat-causing forages.

Bloat also occurs occasionally when cattle are grazed on cereal crops, rape, cabbages, leguminous vegetable crops, including peas and beans, and young grass pasture with a high protein content. An increasing occurrence of bloat is noted when cattle are grazed on young green cereal crops such as winter wheat, especially if it is heavily fertilized and irrigated.

Frothy bloat may also occur in cattle fed alfalfa hay, even when mixed with cereal grains and another hay. Outbreaks are commonly associated with particular lots of hay, often containing fine particles. Alfalfa hay produces a frothy bloat with a typical viscous consistency of the rumen contents but it is commonly more subacute and chronic rather than acute and peracute as in pasture bloat.

**Nonbloating forages**

Bird’s foot trefoil (Lotus corniculatus), cicer milk vetch (Astragalus cicer), arrowleaf clover (Trifolium vesiculosum), sainfoin (Onobrychis vicifolia), and crown vetch (Coronilla varia) are the bloat-safe forages. The bloat-safe forages contain tannins that bind with soluble proteins and inhibit microbial digestion.³

**Condensed tannins (CTs)** or proanthocyanidins comprise polymerized flavan-3-ol-units, and those occurring in temperate forages have a relative molecular mass of 2000–4000, comprising 10–12 units condensed together.⁶ Tannins normally occur in plant vacuoles. CTS from L. corniculatus (bird’s foot trefoil) and Lotus pedunculatus (big trefoil) differ considerably in their chemical structures.

The levels of CTs in big trefoil and bird’s foot trefoil are 45 times greater than in red clover (T. pratense) and 150 times greater than in alfalfa (Medicago sativa).⁸ The protein-precipitating properties of grazing CT-containing legumes has long been known to eliminate bloat. The minimum plant CT concentration needed to make forage bloat-safe has not been discovered but 5 g CT/kg dry matter (DM) or greater has been proposed. Most common legumes and grasses used in temperate agriculture have CT concentrations well below this value, and both conventional plant breeding and genetic engineering techniques are being examined to increase these levels (Table 6.9).

**Crop maturity**

The maturity of the forage is the major plant factor affecting the incidence of pasture bloat.⁹ Grazing very succulent pasture – immature, rapidly growing legumes in the prebloom stage – is the biggest single risk of bloat in cattle.⁴ The bloat potential of alfalfa varies significantly with the phenological stage of the plant. The greatest risk to cattle occurs during the vegetative stage of growth, and the risk declines during the bud stage and may be absent during the bloom stage.⁶ Feeding cattle freshly chopped alfalfa herbage daily at different stages of growth resulted in animal-days of bloat of 62, 10 and 0, respectively, for the vegetative, bud and bloom stages of the alfalfa.⁹ The leaf:stem ratio decreased from 1.2 to 0.5 and 1.5 to 0.4 in two different years as the crop matured from vegetative to bloom stage.⁹ The absence of bloat during bloom can be attributed to the much lower leaf:stem ratio at that stage. As most chloroplasts are within the leaves, the lower leaf:stem ratio at bloom would reduce the concentration of these fragments. A leaf:stem ratio of less than 0.5 (1:2) could be used as an indicator of a low potential for bloat in alfalfa.

**The rapid rate of digestion of the immature bloating forages results in the production of a foam. In the summer months, especially under irrigated conditions when the growth rate of alfalfa is rapid, bloat occurs in cattle fed alfalfa herbage at the vegetative to prebud stages of growth.** Alfalfa’s potential for causing bloat is highest when moisture conditions are optimal for vegetative growth. Under these conditions the stems become turgid and fleshy but not fibrous; the leaves are soft and easily crushed between the fingers. In autumn, the growth rate of alfalfa is slower because of lower temperatures. A rapid rate of growth of the alfalfa is a necessary condition for bloat. Field observations of the relationship between plant factors to alfalfa bloat found that the percentages of dry matter and acid detergent fiber were lower, and the concentration of chlorophyll, total nitrogen and soluble nitrogen were higher on days when bloat occurred.¹⁰

**Ingestion of the more succulent parts of plants and avoidance of the more mature portions can be a precipitating factor and tympany is less likely to occur if the crop is harvested and fed than if it is grazed. Restriction of the grazing area has a similar effect, by forcing the cattle to eat the entire plants. A high incidence is recorded when pasture is wet but this is probably due to the rapid growth of the plants during heavy rainfall periods rather than to the physical wetness of the crop. Under experimental conditions the production of tympany is not influenced by the water content of clover or by wilting. Other plant factors that are known to be associated with an increased tendency to bloat are liberal administration of urea to the pasture, a high intake of glucose, calcium and magnesium, and a high nitrogen intake.**

A high herbage potassium to sodium ratio can increase the risk of bloat in cattle, which may be caused by digestion rate.¹¹ There is some indication that sodium fertilizer can affect the digestion rate of perennial ryegrass and white clover.¹¹ Sodium fertilizer increased maximum gas output from grass and rate of production, which was associated with an increase in grass digestibility; however, in clover it had the opposite effect, thereby potentially reducing bloat in cows fed a high-legume diet.

Results from two decades of bloat research (1973–1993) at Kamloops have been reviewed.⁴ Every cultivar of alfalfa tested in its vegetative to early bloom stages of growth caused bloat. The dry
matter disappearance over the first 6-8 hours was highest in alfalfa that is bloat-inducing. Lower rates of dry matter disappearance were found in saffinoin, bird's foot trefoil and cicer milk vetch, which confirms the bloat-safe features of these alternative legume forages. Bloat was positively associated with the level of fraction 1 protein and total soluble protein in alfalfa, supporting the concept of a decreased probability of bloat with advancing stages of plant maturity. To maintain a high incidence of bloat at the research station, it was necessary to harvest the forage at vegetative to early bloom stages of growth. The risk of bloat was twice as great when the forage height was less than 25 cm than when it was more than 50 cm.

The risk of bloat was reduced by waiting until the dew was off the alfalfa before allowing cattle to graze. This practice of many cattlemen of delaying morning grazing "until the dew has dried". Bloat was observed 2-17 times more often when cattle were fed between 0700 and 0800 hours than when they were fed 4 hours later in both grazing and feedlot trials. Ruminal chlorophyll was higher before the early feeding than before the late feeding, suggesting that feeding later in the morning reduced the predisposition of cattle to bloat by increasing particle clearance from the rumen.

The risk of bloat was also reduced when cattle grazed alfalfa continuously than when grazing was interrupted and cattle were allowed to graze for only 6 hours daily. Pasture management systems that promote continuous and rapid ruminal clearance (more bypass, less gas production) are most likely to reduce the incidence of bloat.

### Weather risk factors

The relationship of weather conditions to the occurrence and incidence of pasture bloat has been examined under Canadian conditions. Under ordinary grazing conditions, bloat occurs sporadically over large parts of the growing season. The occurrence of pasture bloat was not associated with a simple, unique weather variable. The effect of temperature on the incidence of bloat is complex. Bloat seems to occur when moderate daytime temperatures (20-25°C) permit optimum vegetative growth. Cool overnight temperatures in combination with moderate daytime temperatures may induce bloat in the fall. Cool temperatures delay maturation and extend the vegetative growth phase of forage crops, and optimize conditions for bloat. On a daily basis, bloat tended to be preceded immediately by nights and days that were cooler than usual. Bloat can also occur after a killing frost.

#### Feedlot bloat

This occurs in hand-fed cattle confined in feedlots and barns when insufficient roughage is fed or the feed is too finely ground. Two separate sets of circumstances conducive to feedlot bloat have been identified. In one, the cattle are being fed a high-level grain finishing ration in which grain comprises more than 80% of the weight of the ration. The effect of these rations on the rumen is a tendency to acidity and a shortage of rumen-stimulating roughage, which may interfere with motility and eructation. In the other situation, grain comprises 30-70% of the ration, with the same but less marked effect as above, but the roughage component is alfalfa hay with its own bloat-inducing capacity.

#### Animal risk factors

Cattle vary in their susceptibility to primary ruminal tympany, especially that caused by legumes, and this individual susceptibility may be inherited. Cows can be classified according to their susceptibility to pasture bloat into high or low susceptibility and their progeny are similar. Total exchange of rumen contents between high-susceptibility and low-susceptibility animals produces a temporary exchange of susceptibilities that lasts about 24 hours. A number of inherited characteristics are related to bloat. They include ruminal structure and motility, composition of salivary proteins, rate of salivation and the greater capacity of the rumen contents of high-susceptibility animals to degrade mucoproteins that would either reduce antimicrobial activity or increase foam-stabilizing activity. A salivary protein, bSF30, is correlated with susceptibility to bloat in cattle herds selected for high or low bloat susceptibility. One obvious application for such a protein marker for bloat would be to screen cattle to improve of pastures for grazing. For example, it is estimated that bloat costs the dairy industry in New Zealand $50 million annually. The incidence of the disease has increased markedly with the improvement of pastures by heavy applications of fertilizers and the use of high-producing leguminous pasture plants, and losses in cattle at times have reached enormous proportions.

The most obvious form of loss is sudden death. Although this is the dramatic loss, especially when a large number of cattle are unexpectedly found dead, an equivalent loss occurs as the result of reduced food intake. For example, on clover-dominant pasture (60-80% white clover) where bloat was common the weight gains of cattle grazing it were 20-30% less than normal. It has been argued that the returns achieved by good bloat prevention in pastured cattle would not compensate for the costs incurred, but the opposite view is strongly held.

### PATHOGENESIS

Normally, gas bubbles produced in the rumen fluid coalesce, separate from the rumen contents to form pockets of free gas above the level of the contents, and are finally eliminated by eructation. Much of the gas of fermentation and acidification
of bicarbonate will be eructated. A grass-fed cow can produce 100 L during the first hour of feeding. A cow maintained on a legume diet may produce 200 L per hour.21

The composition and kinetics of the gas in the rumen headspace of lactating dairy cattle grazing white clover and perennial ryegrass pastures has been determined.22 Before grazing, rumen headspace gas was composed of carbon dioxide 65%, methane 31%, and nitrogen 4%. After grazing, the headspace gas was composed of carbon dioxide 76%, methane 31%, and nitrogen 3%. The composition of the headspace gas was not affected by antibloat capsules that release 250 mg/d of monensin. The headspace gas from bloated cows contained slightly less carbon dioxide and slightly more nitrogen than that from nonbloated cows.

In frothy bloat, the gas bubbles remain dispersed throughout the rumen contents, producing an abnormal increase in the volume of the ruminoreticulum contents and, consequently, inhibiting eructation. The characteristic frothiness of ruminal contents is caused by inadequate coalescence of gas bubbles.

In free-gas bloat the gas bubbles coalesce and separate from the rumen fluid but the animals cannot eructate the pockets of free gas because of abnormalities of the reticulorumen or esophagus.

Most cases of naturally occurring pasture or feedlot bloat are not accompanied by ruminal atony. In the early stages there is unusually pronounced hypermotility. Most of the gas is mixed with the solid and fluid ruminal contents to form a dense, stable froth. Some free gas is present but the amount that can be removed by a stomach tube or trocar and cannula does little to relieve the distension of the rumen. In general, free-gas bloat characterized by the accumulation of free gas is due to esophageal obstruction or ruminal atony.

If the eructation reflex is functional, the experimental introduction of very large amounts of gas does not cause tympany, since eructation removes the excess. Bloat-producing forages do not produce more gas than safe feeds and the simple production of excessive gas is known not to be a precipitating factor.

Frothiness of the ruminal contents interferes with function of the cardia and inhibits the eructation reflex. Rumen movements are initially stimulated by the distension and the resulting hypermotility exacerbates the frothiness of the ruminal contents. Terminally there is a loss of muscle tone and ruminal motility.

The most distinctive aspect of bloated cattle is abdominal distension, particularly the left abdomen, due to distension of the rumen. Experimentally there is a relationship between reticulorumen volume, intraruminal pressure and the abdomen of cows fed fresh alfalfa.23 The volumes of gas in a bloated cow are large, 50–70 L, and there is an exponential increase in intraruminal pressure with increasing rumen volume, especially as the potential for further increases in the abdomen diminishes. Most severely bloated cows will attempt to urinate and defecate when intraruminal pressures exceed 25 cmH2O but some cows can tolerate pressures in excess of 50 cmH2O. As the intraruminal pressure increases, occlusion of the vena cava occurs, causing congestion of the caudal part of the body. In addition, the pressure exerted by the distended rumen on the diaphragm is very high, which results in reduced lung capacity and death from hypoxia.

CLINICAL FINDINGS

Primary pasture or feedlot bloat

Bloat is a common cause of sudden death (or found dead) in cattle. Pastured beef cattle that die of bloat are usually found dead because they are not observed as regularly as dairy cattle. Feedlot cattle that die of bloat are commonly found dead in the morning, which may be due to their relative inactivity during the night or to the lack of observation, detection and treatment. Dairy cattle that are being milked and observed regularly will commonly begin to bloat within 1 hour after being turned into a bloat-producing pasture. There is commonly a lag period of 24–48 hours before bloating occurs in cattle that have been placed on a bloat-producing pasture for the first time. They may bloat on the first day but more commonly they bloat on the second and third days. A similar situation has been observed in pastured beef cattle, which have been on a particular pasture for several days or weeks before bloat occurs. This is always a surprise to the owner and the veterinarian, who find it difficult to explain why bloat suddenly becomes a problem on a pasture that cattle have grazed safely for some time.

In primary pasture bloat, obvious distension of the rumen occurs quickly, sometimes as soon as 15 minutes after going on to bloat-producing pasture, and the animal stops grazing. The distension is usually more obvious in the upper left paralumbar fossa but the entire abdomen is enlarged. There is discomfort and the animal may stand and lie down frequently, kick at its abdomen and even roll. Frequent defecation and urination are common. Dyspnea is marked and is accompanied by mouth breathing, protrusion of the tongue, salivation and extension of the head. The respiratory rate is increased up to 60/min. Occasionally, projectile vomiting occurs and soft feces may be expelled in a stream.

In mild bloat, the left paralumbar fossa is distended, the animal is not in distress, and 5–7 cm of skin over the left flank is taut but some can be grasped and tented.

In moderate bloat, a more obvious distension of the abdomen is evident, the animal may appear anxious and slightly uncomfortable, and the skin over the paralumbar fossa is usually taut but some can be grasped and tented.

In severe bloat, there is prominent distension of both sides of the abdomen, the animal may breathe into its mouth and protrude the tongue. It is usually uncomfortable, anxious and may be staggering. The skin over the left flank is very tense and cannot be grasped and tented.

Ruminal contractions are usually increased in strength and frequency in the early stages and may be almost continuous, but the sounds are reduced in volume because of the frothy nature of the ingesta. Later, when the distension is extreme, contractions are decreased and may be completely absent. The low-pitched tympanic sound produced by percussion over the rumen is characteristic. Before clinical tympany occurs, there is a temporary increase in eructation, but this disappears in the acute stages. The course in ruminal tympany is short but death does not usually occur in less than 3–4 hours of the onset of clinical signs. Collapse and death almost without struggle occur quickly.

If animals are treated by trocarization or the passage of a stomach tube, only small amounts of gas are released before froth blocks the cannula or tube. In a group of affected cattle, some will be bloated and the remainder have mild to moderate distension of the abdomen. These animals are uncomfortable, graze for only short periods and their milk production is decreased. The drop in production may be caused by depression of food intake or by failure of milk letdown.

Secondary bloat

In secondary bloat, the excess gas is present as a free gas cap on top of the ruminal contents, although frothy bloat may occur in vagus indigestion with increased ruminal motility (see vagus indigestion). There is usually an increase in the frequency and strength of ruminal movements in the early stages followed by atony. Passage of a stomach tube or trocarization results in the release of large
quantities of gas and subsidence of the ruminal distension. If an esophageal obstruction is present it will be detected when the stomach tube is passed.

Dyspnea and tachycardia in severe bloat
In both severe primary and secondary bloat there is dyspnea and a marked elevation of the heart rate up to 100–120/min in the acute stages. A systolic murmur may be audible, caused probably by distortion of the base of the heart by the forward displacement of the diaphragm. This murmur has been observed in ruminal tympany associated with tetanus, diaphragmatic hernia, vagus indigestion and esophageal obstruction and disappears immediately if the bloat is relieved.

CLINICAL PATHOLOGY
Laboratory tests are not necessary for the diagnosis of ruminal tympany.

NECROPSY FINDINGS
In cattle that have died from bloat within an hour previously there is protrusion and congestion of the tongue, marked congestion and hemorrhages of lymph nodes to the head and neck, epicardium and upper respiratory tract, friable kidneys and mucosal hyperemia in the small intestine. The lungs are compressed and there is congestion and hemorrhage of the cervical portion of the esophagus but the thoracic portion of the esophagus is pale and blanched. In general, congestion is marked in the front quarters and less marked or absent in the hindquarters. The rumen is distended but the contents are much less frothy than before death. A marked erythema is evident beneath the ruminal mucosa, especially in the ventral sacs. The liver is pale because of expulsion of blood from the organ. Occasionally, the rumen or diaphragm have ruptured. In animals dead for several hours there is subcutaneous emphysema, almost complete absence of froth in the rumen, and exfoliation of the cornified epithelium of the rumen with marked congestion of submucosal tissues.

TREATMENT
The approach to treatment depends on the circumstances in which bloat occurs, whether the bloat is frothy or due to free gas, and whether or not the bloat is life-threatening.

First-aid emergency measures
Emergency rumenotomy
It is often necessary to advise an owner to use some first-aid measures before the veterinarian arrives on the farm. All animals should be removed immediately from the source of the bloating pasture or feed. In severe cases in which there is gross distension, mouth-breathing with protrusion of the tongue and staggering, an emergency rumenotomy is necessary to save the life of the animal. Once the animal falls down death occurs within a few minutes and many animals have died unnecessarily because owners are unable or reluctant to do an emergency rumenotomy. Using a sharp knife, a quick incision 10–20 cm in length is made over the midpoint of the left paralumbar fossa through the skin and abdominal musculature and directly into the rumen. There will be an explosive release of rumen contents and marked relief for the animal. There are remarkably little contamination of the peritoneal cavity, and irrigation and cleaning of the incision site followed by standard surgical closure usually results in uneventful recovery with only occasional minor complications.

Trocars and cannula
The trocar and cannula have been used for many years for the emergency release of rumen contents and gas in bloat. However, the standard-sized trocar and cannula does not have a large enough diameter to allow the very viscous stable foam in peracute frothy bloat to escape quickly enough to save an animal's life. A larger-bore instrument (2.5 cm in diameter) is necessary and an incision with a scalpel or knife must be made through the skin before it can be inserted into the rumen. If any size of trocar and cannula fails to reduce the intraruminal pressure and the animal's life is being compromised by the pressure, an emergency rumenotomy should be performed. If the trocar is successful in reducing the pressure, the antifoaming agent of choice can be administered through the cannula, which can be left in place until the animal has returned to normal in a few hours. Owners should be advised on the proper use of the trocar and cannula, the method of insertion and the need for a small incision in the skin, and the care of cannulas left in place for several hours or days.

A corkscrew-type trocar and cannula has been recommended for long-term insertion in cases of chronic bloat that occur in feedlot cattle and in beef calves following weaning. The etiology of these is usually uncertain, insertion of a cannula for several days or use of a rumen fistula will often yield good results.

Promote salivation
For less severe cases, owners may be advised to tie a stick in the mouth like a bit on a horse bridle to promote the production of excessive saliva, which is alkaline and may assist in denaturation of the stable foam. Careful drenching with sodium bicarbonate (150–200 g in 1 L of water) or any nontoxic oil as described below is also satisfactory.

Stomach tube
The passage of a stomach tube of the largest bore possible is recommended for cases in which the animal's life is not being threatened. The use of a Frick oral speculum and passage of the tube through the oral cavity permits the passage of tubes measuring up to 2 cm in diameter, whereas this may not be possible if passed through the nasal cavity. In free-gas bloat, there is a sudden release of gas and the intraruminal pressure may return
proximal end of the tube and moving it to normal. While the tube is in place, the antifoaming agent can be administered. In frothy bloat, the tube may become plugged immediately on entering the rumen. A few attempts should be made to clear the tube by blowing through the proximal end of the tube and moving it back and forth in an attempt to locate large pockets of rumen gas that can be released. However, in frothy bloat it may be impossible to reduce the pressure with the stomach tube and the antifoaming agent should be administered while the tube is in place.

If the bloat cannot be relieved but an antifoaming agent has been administered, the animal must be observed closely for the next hour to determine if the treatment has been successful or if the bloat is becoming worse, which requires an alternative treatment.

**Feedlot bloat**

In an outbreak of feedlot bloat, the acute and peracute cases should be treated individually as necessary. There may be many 'swellers', which are moderate cases of bloat that will usually resolve if the cattle are coaxed to walk. After a few minutes of walking they usually begin to eructate. Shaking of experimentally reproduced foam results in loss of stability of foam and coalescence into large bubbles and the movement of walking has the same effect. If walking is effective in reducing the foam, the animals should be kept under close surveillance for several hours for evidence of continued bloating, which is unusual.

**Antifoaming agents**

Details of oils and synthetic surfactants used as antifoaming agents in treatment are described in the section on control because the same compounds are used in prevention. Any nontoxic oil, especially a mineral one that persists in the rumen, not being biodegradable, is effective and there are no other significant differences between them. Their effect is to reduce surface tension and foam. A dose of 250 mL is suggested for cattle but doses of up to 500 mL are commonly used. An emulsified oil or one containing a detergent such as diocetyl sodium sulfosuccinate is preferred because it mixes effectively with ruminal contents. Of the synthetic surfactants, poloxalene is the one in most general use for leguminous bloat and a dose of 25⁻50 g is recommended for treatment. It is not as effective for feedlot or grain bloat. Alcohol ethoxylates are a promising new group of compounds for use as bloat remedies and both poloxalene and the ethoxylates are more effective and faster than oil, which is relatively slow and better suited to prevention than treatment. All three are recommended as being satisfactory for legume hay bloat, but poloxalene is not recommended for feedlot bloat. All of them can be given by drench, stomach tube or through a ruminal cannula. The effect of all is enhanced if they are thoroughly mixed with the ruminal contents; if rumen movements are still present mixing will occur. If the rumen is static it should be kneaded through the left flank.

Alfasure (a water-soluble pluronic detergent) is effective for the treatment of alfalfa bloat when 30 mL is given intraruminally using a 6 cm 14-gauge hypodermic needle directly into the rumen through the abdominal wall in the middle of the paralumbar fossa. The median time of disappearance after treatment was 25 minutes; the swelling returned to normal within 52 minutes.

**Return to pasture or feed**

Following the treatment of the individual cases of bloat the major problem remaining is the decision about whether or not, or when, or under what conditions, to return the cattle to the bloat-producing pasture or to the concentrate ration in the case of feedlot cattle. The possible preventive measures are presented under control but, unless one of the reliable ones can be instituted, the cattle should not be returned until the hazardous period has passed. This is difficult on some farms because the bloat-producing pasture may be the sole source of feed.

**CONTROL**

**Pasture bloat**

Management strategies to reduce rate of rumen fermentation. The prevention of pasture bloat is difficult. Grazing management strategies are the principal methods used for the prevention of pasture bloat, along with controlling pasture yields and quality. Several different management practices have been recommended, including the prior feeding of dry, scabrous hay, particularly sudan grass, cereal hay and straw, restricting the grazing to 20 minutes at a time or until the first cow stops eating, harvesting the crop and feeding it in troughs, and strip grazing to insure that all available pasture is utilized each day.

The principle of each of these strategies is to decrease the rate of rumen fermentation. These methods have value when the pasture is only moderately dangerous but may be ineffective when the bloat-producing potential is high. In these circumstances the use of simple management procedures is unreliable because the occurrence of bloat is unpredictable. In other cases, the strategies such as limited grazing are impractical. Generally, the farmer does not know if the pastures are dangerous until bloat occurs and, once effective prophylactic methods are being used, it is difficult to know when they are no longer required. The bloat-producing potential of a pasture can change dramatically almost overnight and the management strategy can be quickly nullified.

**Stage of growth**

The probability of legume bloat decreases with advancing stages of plant maturity due to a decrease in the soluble protein content of the legume. Alfalfa at the vegetative stage of growth results in the highest incidence of bloat compared with the bud and bloom stages, with moderate and no bloat, respectively. These results indicate the potential for grazing management through selection of plant phenology (periodic phases of plant growth) as a method of bloat control. In practice, it would be essential to recognize the predominant stage of growth of the stand before turning cattle into the pasture. The leaf/stem ratio should also be considered as a factor.

**Choice of forages**

Seeding cultivated pastures to grass–legume mixtures is the most effective and least costly method of minimizing pasture bloat, particularly for beef herds grazing over large areas under continuous grazing systems. In a grass–legume mixture, a legume content of 50% is suggested as the maximum bloat-safe level. However, this ratio may be impractical for large areas, especially on rolling terrain, where it is impossible to maintain a uniform 50:50 stand. If cattle have a tendency to avoid the grass and select the legume, the potential for bloat increases. Bloat can occur in mixed pastures where the proportion of legume is less than 15%, possibly because of selective grazing.

Because of the potential for causing bloat, grasses alone or nonbloating forages may be used. Sainfoin, bird's-foot trefoil, cicer milk vetch and crown vetch are useful bloat-safe legumes in regions where they are adapted. However, their yield, vigor, regrowth, winter-hardiness and persistence are well below the superior growth and production characteristics of alfalfa. Seeding grasses alone avoids the problem of bloat but the benefits of including a legume in the mixture include much greater production, higher protein and nutritional value and lower fertilization costs. A decision to use grass with or without bloat-safe legumes should be based on the economic benefits of the greater protein from alfalfa or clover compared with the possible losses from bloat.

At present, a pasture comprising equal quantities of clovers and grasses comes...
Research work in this area is directed towards selecting cattle that are more susceptible to bloat. More practical are the moves being made to breed varieties of legume that are low on bloat-producing potential.

The incidence of frothy bloat can be substantially reduced if alfalfa herbage contains as little as 25% orchardgrass.\textsuperscript{36}

**Condensed tannins in forages**

Proanthocyanidins, also known as CTs, are phenolic plant secondary compounds widely distributed through the plant kingdom, especially in woody plants and in certain forages.\textsuperscript{27} In ruminants fed high-quality fresh forage diets (25–35 g nitrogen (N/kg DM) and 10–11 MJ of metabolizable energy (ME)/kg DM) most proteins are rapidly solubilized and released between 56% and 65% of the N concentration in the rumen during mastication; consequently large losses of nitrogen occur (250–25%) as ammonia is absorbed from the rumen. Thus, the inefficient use of nitrogen by ruminants needs research to focus on improving nitrogen retention by the animal and natural plant compounds with known ability to reduce proteolysis, such as CTs, which exert their effects by complexing with proteins.

Forages containing moderate concentrations of CTs can exert beneficial effects on protein metabolism in sheep, slowing degradation of dietary protein to ammonia by rumen microflora and increasing protein outflow from the rumen, thus increasing absorption of amino acids in the small intestine of the animal. This can result in increases in lactation, wool growth and live weight gain, without changing voluntary feed intake. Dietary CTs can also contribute to improved animal health by reducing the detrimental effects of internal parasites in sheep and the risk of bloat in cattle. In contrast, high dietary CT concentrations (6–12% DM) depress voluntary feed intake, digestive efficiency and animal productivity.\textsuperscript{39}

The literature on the effect of CTs on the nutrition and health of ruminants fed fresh temperate forages has been reviewed.\textsuperscript{39} Forages containing substantial amounts of CTs are nonbloating because of the protein-precipitating properties of CTs.\textsuperscript{34,35} CTs interact with proteins in feed, saliva and microbial cells, with microbial enzymes and with endogenous proteins and other feed components, which alters digestive processes compared with diets free from CT.\textsuperscript{39} Tannin levels exceeding 40–50 g/kg DM in forages may reduce protein and DM digestibility of the forages by ruminants. At low to moderate levels, CTs increase the quantity of dietary protein, especially essential amino acids, flowing to the small intestine. Unlike alfalfa, legumes that contain CTs do not cause bloat. Dietary CTs may provide a means to beneficially manipulate protein digestion and/or prevent pasture bloat in ruminants.

White clover and alfalfa (lucerne) contain only trace amounts of CTs in their leaves but are used extensively in animal production because of their high nutritive value. A minimum concentration of 5 g/kg DM of CTs is necessary for a high probability of preventing bloat. The transfer of DNA coding for CT production in leaves from plant species such as lotus, sulla and sainfoin into legumes such as white clover and alfalfa that normally only express low levels of CTs in leaf tissue has been proposed. Investigations to produce alfalfa and white clover containing 5 g CT/kg DM using gene transfer technology have been conducted in Australia and Canada with the objective of producing a nonbloating alfalfa cultivar.\textsuperscript{30} Concentrations of 0.75–1.25 g CT/kg DM have been achieved but are well below the value of 5 g/kg DM estimated to reduce bloat.

**Alternative temperate forages**

The literature on the use of alternative temperate forages to improve the sustainable productivity of grazing ruminants, relative to grass-based pastures has been reviewed.\textsuperscript{30}

Forages comprise a major proportion of the diet in most ruminant animal production systems. Grazed forages are used especially during the late spring, summer and autumn in many countries, while in some regions such as Australasia and South America, ruminant animal production is based on year-round grazing of forages, with no indoor housing. Grazing systems are generally based on swards of which the major portion consists of grasses (perennial ryegrass (Lolium perenne) in the case of New Zealand), with a legume (white clover (T. repens) in the case of New Zealand) forming a minor portion (approximately 20%), mainly to fix atmospheric nitrogen and to provide a higher-quality feed. Different grasses and legumes form the grazed pastures in other countries. The grazing of alternative forages is being developed for the sustainable control of internal parasites, with reduced anthelmintic use, for increasing reproductive performance in sheep and the growth rate in young animals, and for reducing the incidence of bloat in cattle.\textsuperscript{30}

It has been long accepted in ruminant nutrition that the feeding value of legumes is greater than that of grasses, owing to their more rapid particle breakdown, faster rumen fermentation, lower rumen mean retention time and consequently greater voluntary feed intake. Despite these advantages, legumes have never attained their true potential in many grazing systems because of three principal disadvantages: legumes generally grow slowly in winter, producing less feed per hectare than grasses; rumen frothy bloat in cattle is caused by rapid solubilization of protein in many legumes; and the presence in some legumes of estrogens depresses reproductive performance when grazed by ewes during the breeding season. Thus the identification of legumes that could overcome these limitations would offer major advantages. The herb chicory (Chicorium intybus) and the CT-containing legumes bird’s foot trefoil (L. cruciatus) and sulla (Hedyarum coronarium) offer the most advantages.\textsuperscript{20}

Chicory and sulla promoted faster growth rates in young sheep and deer in the presence of internal parasites, and showed reduced methane production. Grazing on L. cruciatus was associated with increases in reproductive rate in sheep, increases in milk production in both ewes and dairy cows and reduced methane production, effects that were mainly due to its content of CTs. The risk of frothy bloat in cattle grazing legumes is reduced when the forage contains 5 g CT/kg DM or greater.

The degree to which sulla, chicory and bird’s foot trefoil are adopted by livestock farmers will depend upon their agronomy under grazing, as well as their nutritive and feeding values. All three have no means of vegetative propagation under grazing and thus plant density declines with time. With careful management, such as not grazing during wet winter weather, stands of chicory can last 4–6 years under New Zealand conditions and is gaining acceptance by farmers. Chicory is often seeded with a legume such as red clover, which has a similar lifespan and fixes nitrogen. L. cruciatus is best suited to hot, dry summer climates and warm winter climates and stands will persist for 3–4 years under these conditions, indicating a role in future dryland grazing systems. When grown in environments that have regular summer rainfall, a stand of L. cruciatus lasts only 2 years, as a result of competition from grasses, volunteer legumes and weeds.\textsuperscript{20} Sulla is biennial, with a life of one winter and two grazing seasons; it has a specialized requirement for inoculation with Rhizobium bacteria. These factors and the lack of commercial seed supply have reduced the
acceptance of sulla by livestock producers in New Zealand, despite its obviously high nutritive value and high feeding value.

Nonbloating alfalfa cultivars
Based on research initiated in western Canada in the 1970s, alfalfa cultivars have been selected with a low potential for bloating based on low initial rates of digestion. In field trials, a new alfalfa cultivar (AC Grazeland) reduced the incidence and severity of bloat on pasture compared with the control cultivar Beaver. The initial rate of digestion was 85% of unselected alfalfa, and the incidence of bloat at three locations over 3 years was significantly reduced. However, the new cultivars are not bloat-safe; they are bloat-reduced cultivars.

Field management
Fertilization and grazing management may be used to maintain a 50:50 mixture of grass and alfalfa. Nitrogen fertilizer and heavy or frequent grazing promote grass growth at the expense of alfalfa. In areas where the incidence of bloat is high, the critical upper limit of alfalfa may be as low as 25–30%. In addition to seeding alfalfa to form 25–30% of the total stand, mixtures grown in sandy areas, which are more prone to drought than heavy soils, are less likely to produce bloat. Although alfalfa-grass mixtures may be seeded to produce the desired proportion of alfalfa and grass, selective grazing and variation in the terrain of the field may allow excessive intake of alfalfa, resulting in bloat. The period following mechanical harvesting or intensive grazing of alfalfa-grass mixtures may pose a potential risk of bloat, because alfalfa generally recovers faster than grass after cutting.

The ideal companion grass should have the same seasonal growth pattern and regrowth characteristics as alfalfa. Smooth bromegrass is widely grown in a mixture with alfalfa but its regrowth after grazing or cutting is lower than alfalfa. Consequently, pasture bloat may occur when an alfalfa-bromegrass mixture is used in rotational grazing systems. Sufficient time must elapse between rotations to allow regrowth of the bromegrass.

Meadowgrass has faster regrowth than smooth bromegrass. Similarly, orchardgrass and timothy have fast regrowth characteristics and are the best choices in areas where they are adapted.

Grazing management
Uniform and regular intake is the key to managing cattle on legume pastures. Waiting until the dew is off before placing animals on pasture is a common practice and is probably useful when animals are first exposed to a legume pasture. Before animals are placed on a legume pasture they should be fed coarse hay to satiate. This prevents them from gorging themselves and overeating the fresh and lush legume forage. Thereafter, they should stay on the pasture. Mild bloat may occur on first exposure, but the problem should disappear in a few days because animals usually adapt to legume pastures with continuous grazing. If the legume pasture continues to have a high bloat potential, the animals should be removed until the legume becomes more mature and less bloat-provoking.

Forage supplements prior to grazing
The effect of feeding a forage supplement such as chopped straw combined with cane molasses and soyabean meal to dairy cattle prior to being placed on a clover pasture twice daily has been examined as a strategy to reduce the incidence of bloat. The energy and protein content were varied by the content of molasses and soyabean meal. A high-energy, high-protein supplement increased the incidence of bloat, and a low-energy, high-protein supplement reduced the incidence compared to grazing alone. The feeding of silage prior to grazing reduced the incidence of bloat among cows grazing both tall and short swards. The most suitable forages to feed when there is a risk of bloat are those that are slowly fermented in the rumen but are eaten in sufficient quantity to reduce periods of rapid forage intake.

Grazing patterns and strip grazing
Bloat is often associated with discontinuous grazing such as removal of animals from the legume pasture for a period of time, e.g. overnight. Similarly, outbreaks may occur when grazing is interrupted by adverse weather, such as storms, and by biting flies or other insect pests. These factors alter normal grazing habits, generally resulting in more intensive, shorter feeding periods that may increase the incidence of bloat.

In strip grazing the field is grazed in strips that are changed every 1–3 days. This is done by careful placement of an electric fence so that the grazing strip is moved further and further away from the entrance. In this way the animals are forced to graze a greater proportion of the entire plant, which increases the dry matter intake and proportionately decreases the intake of soluble protein, which results in a decrease in the rate of digestion in the rumen. In some situations, the most reliable methods for the prevention of bloat in dairy cows are either strip grazing of pasture sprayed daily with oil or phluronic, or twice-daily drenching with the same preparations.

Swathing and wilting
The frequency of alfalfa bloat can be decreased by grazing pastures that have been swathed and wilted. Wilting swathed alfalfa for 24 hours produces changes in the protein configuration of the sulphydryl and disulfide content of the proteins. Compared with feeding a fresh swath, wilting a swath for 24 or 48 hours reduces the incidence of alfalfa bloat. The reduction is greatest by 48 hours and may be eliminated after 48 hours. A reduction in moisture content during wilting may be sufficient to eliminate the risk of bloat. Alfalfa silage is virtually bloat-free because of protein degradation by proteolysis during ensiling.

Alfalfa hay bloat prevention
The bloat-potential of alfalfa hay is unpredictable. The best indicators are leafy, immature hay with soft stems. Hay grown under cool, moist conditions is more likely to cause bloat than hay produced in hot, dry areas. Reports of bloat on damp, moldy hay are common but not documented and are unexplained. Since fine particles and leaves are especially dangerous, chopping hay can increase the incidence of bloat.

When alternative roughages are available, a coarse grass hay, cereal grain hay or straw can be substituted for a portion of the bloat-causing hay. In dairy herds, alfalfa hay can be fed in the morning and grass hay in the evening. Animals should be adjusted gradually to new lots of alfalfa hay; old and new lots should be mixed for the first 5 days of feeding.

Rations containing a 50:50 mixture of alfalfa hay and grain are most dangerous but the risk of bloat is low when grain consists of less than 35% of the mixture.

Antifoaming agents
One satisfactory strategy for the prevention of pasture bloat is the administration of antifoaming agents.

Oils and fats
Oils and fats have achieved great success for the control of pasture bloat in New Zealand and Australia.

Individual drenching
Individual drenching is sometimes practiced but because of the time and labor involved it is most suited to short-term prophylaxis. It is popular as an effective standard practice in pastured cattle in New Zealand. The common practice is to administer the antifoaming agent (antibloat drench) at the time of milking using an automatic dose syringe that is moved up and down to reach each cow in the milking parlor. Cows become conditioned quickly and turn their heads to the operator to receive their twice-daily dose of 60–120 mL of the oil. The duration of the foam-preventing effect is short.
lasting only a few hours, and increasing the dose does not significantly lengthen the period of protection.

The combined use of sodium chloride and antioil drenching of lactating dairy cows in New Zealand may stimulate the closure of the reticular groove, causing the swallowed fluid to bypass the reticulo-rumen, rendering the drenching with the antioil solution ineffective.34 The proportion of antioil—sodium-chloride fluid bypassed was considered to be of no practical significance to the protection of the rumen, lasting only a few hours, and increasing the period of protection. However, there may be decreased protection in 10–15% of drenched cows. Thus, cows should be drenched with these compounds at separate times, morning for one, evening for the other, or, if drenching at the same milking, drench with the antioil solution first, followed by a separate drench with sodium chloride.

Application of oil to pasture

If the oil or fat is emulsified with water it can be sprayed on to a limited pasture area that provides part or all of the anticipated food requirements for the day. Backgrazing must be prevented and care is required during rainy periods when the oil is likely to be washed from the pasture. The method is ideal where strip-grazing is practiced on irrigated pasture but is ineffective when grazing is uncontrolled.

Addition to feed and water

The oil can be administered at the rate of 120 g per head in concentrates fed before the cattle go on to the pasture or by addition to the drinking water to make a 2% emulsion. Oil can be added to water in all available troughs, turning off the water supply and refilling the troughs when they are emptied. However, the actual intake of the oil cannot be guaranteed. Climatic conditions also cause variations in the amount of water that is taken, with consequent variation in the oil intake. Thus it is best to make provision for a daily intake of 240–300 g of oil per head during those periods when the risk of bloating is highest. The recommended procedure is to provide an automatic watering pump that injects antioil agents into all the drinking water supplies in amounts that will maintain a concentration of 1% of the antioil agent. Hand replenishment means that the preparation must be added twice daily. Surfactants are preferred to oils because of their faster action, the smaller dose rates (5–8 mL in 10–20 mL of water) and their longer period of effectiveness (10–18 h).

Application to flanks

Antioil agents can be applied with a large paint brush to the flanks of cows as they go out of the milking shed. A preparation that is palatable to cattle and encourages them to lick their flanks is preferred. This has been a popular method of controlling bloating in dairy cows in Australia, but failures are not infrequent, especially in individual cows.

Types of oil

Many different oils have been used and most vegetable oils, mineral oil and emulsified tallow are effective. The choice of oil to be used depends on local availability and cost. If the oils are to be used over an extended period, some consideration must be given to the effects of the oil on the animal. Continued administration of mineral oil causes restriction of carotene absorption and reduces the carotene and tocopherol content of the butter produced. Linseed oil, soya oil and whale oil have undesirable effects on the quality and flavor of the milk and butter. Peanut oil and tallow are the most satisfactory. In most areas the tympany-producing effect of pasture is short-lived and may last for only 2–3 weeks. During this time the pasture can be grazed under the protection of oil administration until the bloating-producing period is passed.

Water-soluble feed supplements

Commercially available sources of CTs, and plant extracts of Yucca schidigera (yucca) are a natural source of steroidal saponins.35 Both compounds were ineffective in preventing bloating in cattle fed fresh alfalfa herbage when used as a water-soluble feed supplement added to the drinking water or given as a top-dressing.

Synthetic non-ionic surfactants

Poloxalene

Poloxalene is a non-ionic surfactant (surface active agent) that has been used successfully for the prevention of leguminous bloating for 25 years.36 It is a polyoxyethylene polyoxypropylene block polymer and highly effective for use in cattle grazing lush legume pasture or young cereal crops such as wheat pasture. Poloxalene moderates the digestive behavior of cattle grazing immature alfalfa.37 In cattle the recommended daily level of poloxalene for prevention of bloating is 2 g/100 kg BW. In high-risk situations it may be advisable to administer the drug at least twice daily. Poloxalene is unpalatable and its use in drinking water was not possible until the introduction of the pluronic L64, which is suitable for mixing with drinking water and is effective. It has to be introduced to the cattle several weeks before the bloating season commences. It is commonly used as an additive to grain mixtures, in feed pellets and in mineral blocks. The use of pluronic administered by mixing with molasses to be licked from a roller drum was popular for a short period of time for the control of bloating in pasture beef cattle but consumption was erratic and control of bloating unreliable. The alternative of mixing pluronic with the drinking water is also not dependable. Pluronic poisoning has occurred in grass- and milk-fed young calves given a pluronic-type detergent bloating drench because the attendant thought the calves were mildly bloated.38 Dyspnea, bellowing, convulsions and death in 24 hours occurred.

Alfasure

Alfasure, a polyoxypropylene-polyoxyethylene glycol surfactant polymer, is very effective for the prevention of bloating when used at 0.05% in drinking water of cattle fed fresh alfalfa herbage and when added as a top dressing.39 An Alfasure spray on pasture is completely effective in eliminating the occurrence of bloating in cattle grazing alfalfa at the vegetative to bud stage of growth.33

Alcohol ethoxylate detergents

These products are known to have equal foam-reducing qualities to poloxalene and have the advantage of better palatability so that they can be administered by a voluntary intake method such as medicated blocks. Small-scale field trials show that these blocks are palatable and attractive and should be satisfactory in reducing the severity and prevalence of bloating. Not all cattle visit them voluntarily, so some cases of bloating are likely to occur. The blocks contain 10% of the alcohol ethoxylate, known as Teric, and a daily consumption of 17–19 g of it is usual. Application of Teric to the flanks of cows has not been as successful as a bloating prevention as has similar application of oils.

Alcohol ethoxylate and pluronic detergents controlled the occurrence of bloating in sheep fed freshly harvested alfalfa in confinement and in grazing studies wherein the products were added to the water supply.40 In cattle grazing early to late bud alfalfa stands, the addition of the products to the water supplies prevented the occurrence of bloating.

Ionophores

Rumen modifiers such as the ionophore monensin have been used to control bloating using controlled-release capsules and liquid formulations.40

Controlled-release monensin capsules

Sustained-release capsules containing antifoaming agents are available for the control of pasture bloating. The capsule is administered into the rumen, where it opens, exposing an antifoaming agent, which diffuses slowly from a matrix.
Monensin, a polyether ionophore antibo-tic, is potentially an important agent for bloat relief in dairy cows grazing legume-based pasture.17 A monensin controlled-release intraruminal capsule is available that releases approximately 300 mg/head per day for 100 days.15 Experimental and field studies indicate that monensin can reduce the severity of bloat and increase milk production in dairy cows grazing legume pastures.17 In dairy farms in Australia, sustained-release monensin capsules were effective in reducing the incidence of clinical bloat in pasture-fed cattle.41 There was also a significant decrease in the use of pasture spraying, drinking water administration and flank-spraying of antifoaming agents on the farms using the capsules, with no compensatory rise in the use of other bloat-prevention techniques.

A controlled-release monensin capsule reduced the incidence of bloat by about 50% in experimental steers fed alfalfa at the vegetative to early bud stages of growth.17

**Liquid formulation of monensin**

Oral drenching with a liquid formulation of monensin is effective in reducing bloat in milking cows grazing white-clover-ryegrass or red-clover pastures.40 A daily dose of 300 mg per cow given as an oral drench in a volume of 100 mL daily provided protection for 24 hours.

**Feedlot bloat**

Roughage in ration

Feedlot high-level grain rations should contain at least 10–15% roughage, which is cut or chopped and mixed into a complete feed. This ensures that cattle will consume a minimum amount of roughage. The roughage should be a cereal grain straw or grass hay. The use of leafy alfalfa hay may be hazardous. The roughage may be fed separately in the long form as a supplement to the grain ration but this practice is dangerous because the voluntary intake of roughage will vary considerably. The more palatable the grain ration, the less total roughage will be eaten and outbreaks of feedlot bloat may occur.

Consistency of grain

Best results in feedlot bloat are achieved by the incorporation of nonbloating roughages in the grain ration at a level of at least 10%, and avoiding fine grinding of the grain. Grains for feedlot rations should be only rolled or cracked, not finely ground. If the grain is very dry, the addition of water during processing will prevent pulverization to fine particles. The use of pelleted rations for feedlot cattle cannot be recommended because a fine grind of the grain is normally necessary to process a solid pellet. When the pellet dissolves in the rumen, a fine pasty rumen content forms, which may be associated with the development of a stable foam. In addition, it is difficult to incorporate a sufficient quantity of roughage into a pellet.

**Antifoaming agents**

The use of dietary antifoaming agents for the prevention of feedlot bloat has had variable success. The addition of tallow at the level of 3–5% of the total ration has been successful, judged empirically, but controlled trials did not reduce bloat scores.17 If animal fats are effective in preventing feedlot bloat they would be useful as a source of energy and for the control of dust in dusty feeds. Poloxalene is ineffective for the prevention of feedlot bloat.

**Dietary salt**

The addition of a 4% salt to feedlot rations has been recommended when other methods are not readily available. However, feed intake and rate of body weight gain will be reduced. A high salt diet increased water intake, causes an alteration in the proportion of disrupted cells in the forage due to changes in fermentation, and increases the rate of flow of particulate material out of the rumen. Other management factors considered to be important in the prevention of feedlot bloat generally include: avoid overfeeding after a period of temporary starvation, e.g. after bad weather, machinery failure, transportation or feed handling failure, and insure that the water supply is available at all times.

**Genetic control of pasture bloat**

Because of the high costs of bloat from deaths, lost production, treatment costs and extra labor, one possible long-term solution is to breed cattle with reduced susceptibility to bloat.14 Bloat score on a single day is heritable but the required testing procedures are expensive in labor and can put the lives of otherwise valuable animals at risk. Selection on bloat score has been achieved successfully in an experimental herd, and genetic markers and candidate genes for bloat susceptibility are now being explored.14 The ultimate aim is to assist the dairy industry to identify bloat-susceptible animals, so that they can be culled or used less frequently as parents in the national herd. Work in New Zealand suggests that the prospects are good for providing the dairy industry with a means of removing bloat-susceptible cattle. Carrier sires could be identified, using a marker, and these sires could be withheld from the teams of widely used proven sires available for commercial use. The use of non-carrier artificial insemination sires in the dairy cattle industry could minimize the bloat problem in one generation, by removing all homozygous bloat-susceptible progeny from the population.14 There has been no recent research on this aspect of bloat in cattle.

**General comments**

Apart from the impressive reduction in clinical and fatal cases of ruminal tympany resulting from the prophylactic use of oils, there are the added advantages of being able to utilize dangerous pasture with impunity and the reduction of subclinical bloat and its attendant lowering of food intake. Production may rise by as much as 25% in 24 hours after the use of oil. Nevertheless, these preventive methods should be considered as temporary measures only. The ultimate aim should be the development of a pasture of high net productivity where the maximum productivity is consistent with a low incidence of bloat and diarrhea.

TRAUMATIC RETICULOLEMENTITIS

Perforation of the wall of the reticulum by a sharp foreign body initially produces an acute local peritonitis, which may spread to cause acute diffuse peritonitis or remain localized to cause subsequent damage, including vagal indigestion and diaphragmatic hernia. The penetration of the foreign body may proceed beyond the peritoneum and cause involvement of other organs resulting in pericarditis, cardiac tamponade, pneumonia, pleurisy and mediastinitis, and hepatic, splenic or diaphragmatic abscess. These sequelae of traumatic perforation of the reticular wall are set out diagrammatically in Figure 6.4.

This complexity of development makes diagnosis and prognosis difficult, and the possibility that a number of syndromes may occur together further complicates the picture. All these entities except endocarditis are dealt with together here, even though many of them are diseases of other systems.

ETIOLOGY

Traumatic reticulolementitis is caused by the penetration of the reticulum by metallic foreign objects that have been ingested in prepared feed. Baling or fencing wire that has passed through a chaff-cutter, feed chopper or forage harvester is one of the most common causes. In one series of 1400 necropsies, 59% of lesions were caused by pieces of wire, 36% by nails and 6% by miscellaneous objects. The metal objects may be in the roughage or concentrate or may originate on the farm when repairs are made to fences, yards and in the vicinity of feed troughs.

The wire from motor vehicle radial tires may be the cause.1-3 Used tires are commonly used to hold down plastic sheeting over silage piles. The wire is gradually released from the tires, which are in a state of deterioration, and is mixed with the feed supply, or the tires may be inadvertently dropped into a feed mixer wagon and become fragmented, mixing the pieces of wire throughout the ration.

![Fig. 6.4 Sequelae of traumatic perforation of the reticular wall.](image-url)
In an abattoir survey of the gastrointestinal tract of 1491 slaughter cows in Denmark, foreign bodies were found in 16% of the cows. Of 286 foreign bodies, 11% were tire wires, 14% fencing wires, 5% screws, 9% nails, 37% mixed pieces of metal, 2% copper and 22% remnants of boluses containing antiparasitic drugs. A significant association was found between the type of foreign body and the presence of lesions, and a significant association between the cross-section of the foreign body and the presence of lesions. There was also an association between the end shape of the foreign body and the presence of lesions. Tire wire was the most common traumatizing foreign body, as 81% of all lesions were associated with tire wires.

**EPIDEMIOLOGY**

**Occurrence**

Adult dairy cattle are most commonly affected because of their more frequent exposure but cases occur infrequently in yearlings, beef cattle, dairy bulls, sheep and goats. In the series of 1400 referred to above, 93% were in cattle over 2 years old and 87% were in dairy cattle. In the Danish abattoir survey of cows (see Etiology), foreign body lesions were present in 10% of the cows. Magnets, one or two, were found in only 7% of the cows. All magnets collected iron filings and fencing wire (30%), and “other pieces of metal” (39%) were the predominant contents of the magnet. There were no lesions in 97% of the cows with magnets, and a significant association was found between the use of magnets and the absence of lesions.

The disease is much more common in cattle fed on prepared feeds, especially those fed inside for part of the year. It is almost unknown in cattle fed entirely on pasture. Accordingly, it is much more common in the winter months in the northern hemisphere. The incidence is low in sheep and goats.

The incidence is usually sporadic but outbreaks have occurred when sources of wire have become mixed into feed supplies, as in the case of perforation of the alimentary tract by pieces of tire wire. Over a period of 6 months, 30% of 170 lactating dairy cows in one herd exhibited clinical signs suggestive of hardware disease associated with the ingestion of tire wire in the feed supplies.

**Risk factors**

There are few studies of the epidemiology of traumatic reticuloperitonitis. The effects of 23 veterinary diagnoses, host characteristics and production were examined on the risks of ruminal acidosis and traumatic reticuloperitonitis. The total incidence risk for the disease in Finnish Ayrshire dairy cattle was 0.6%, which is similar to observations made in Holstein-Friesian cows. The risk of the disease in the former study increased with early metritis, nonparturient paresis, ketosis, acute and chronic mastitis, and foot and leg problems. It is unknown how metritis and mastitis could be risk factors for traumatic reticuloperitonitis. The median day of occurrence was on 113 days after calving, which makes it unlikely that calving was a risk factor. Similarly, dystocia was not found to be a risk factor.

When several or more cases occur in a cluster outbreak, the nature of the feed supply should be considered as a risk factor. The use of used tires to secure plastic sheeting over silage piles may be an important risk factor.

**Economic importance**

The disease is economically important because of the severe loss of production it causes and the high mortality rate. Many cases go unrecognized and many more make spontaneous recoveries. In industrialized countries, metallic foreign bodies may be present in the reticulum in up to 90% of normal cattle and residual traumatic lesions may be present in as many as 70% of dairy cows. Among the clinically affected animals, about 25% develop incurable complications. The other 75% can be expected to recover completely with conservative treatment or routine surgical intervention.

**PATHOGENESIS**

**Ingestion of foreign body**

Lack of oral discrimination by cattle leads to the ingestion of foreign bodies that would be rejected by other species. Swallowed foreign bodies may lodge in the upper esophagus and cause obstruction or in the esophageal groove and cause vomiting, but in most instances they pass to the reticulum. Radiological examination of goats that have been fed foreign bodies experimentally indicate that they may first enter various sacs of the reticulorumen before reaching the reticulum. Many lie there without causing harm but the honeycomb-like structure of the reticulum provides many sites for fixation of the foreign body, and contractions of the reticulum are sufficient to push a sharp-pointed object through the wall.

**Penetration of reticulum**

Most perforations occur in the lower part of the cranial wall of the reticulum but some occur laterally in the direction of the spleen and medially towards the liver.

If the reticular wall is injured without penetration to the serous surface no detectable illness occurs, and the foreign body may remain fixed in the site for long periods and gradually be corroded away.
A piece of wire can disappear in 6 weeks but certain nails last much longer and are unlikely to corrode away in less than 1 year. The ease with which perforation occurs has been illustrated by the artificial production of the disease. Sharpened foreign bodies were given to 10 cows in gelatin capsules. Of 20 pieces of wire and 10 nails, 25 were found in the reticulum. Of the 20 pieces of wire 18 had perforated or were embedded in the wall or plicae. Only one of the nails was embedded. Complete perforations were caused by 13 foreign bodies and incomplete by six. All cows suffered at least one perforation, showed clinical signs of acute local peritonitis and recovered after surgical removal of the foreign bodies.

Many foreign bodies may not remain embedded but are commonly found free in the reticulum if surgery is carried out about 72 hours after illness commences. This may be due to necrosis around the penetrating object and the reticular contractions moving the foreign body back into the reticulum. Objects that are deeply embedded or have kinks, bars or large diameters tend to remain in situ and cause persistent peritonitis.

**Acute local peritonitis**
The initial reaction to perforation is one of acute local peritonitis and, in experimentally induced cases, clinical signs commence about 24 hours after penetration. The peritonitis causes ruminal atony and abdominal pain. If the foreign body moves back into the reticulum spontaneous recovery may occur.

**Resolution of acute fibrinous local peritonitis** is characterized by the development of fibrous adhesions, which gradually become long, stringy strands over a period of weeks and months, motility of the reticulum is restored and the animal may recover fully. Follow-up ultrasonographic examinations of cows with traumatic reticuloperitonitis in which rumenotomies were done found that the adhesions disappeared in most of the animals by 6 months.

Depending on the severity of the local peritonitis, the ventral aspect of the reticulum becomes adherent to varying degrees to the abdominal floor and diaphragm. This results in decreased reticular motility. Ultrasoundography of cows with traumatic reticuloperitonitis reveals that the biphasic contractions of the reticulum are slower than normal or indistinct and the number of contractions are reduced. Reticular abscesses are common complications and may be located between the reticulum and the ventral body wall, between the reticulum and the right thoracic wall and between the reticulum and the spleen. Persistent local peritonitis with or without abscesses results in reduced reticular motility, inappetence to anorexia, a capricious appetite (may eat hay not concentrate), chronic ruminal tympany, persistent mild fever, abdominal pain on deep palpation, and changes in the hemogram and feces. Immobilization of the reticulum impairs the clearance function of the reticulum, which results in the passage of poorly comminuted feces characterized by an increased proportion of large particles.

**Generalized peritonitis and extension of disease**
Spread of the inflammation causing generalized or diffuse peritonitis may occur in cows that calve at the time of perforation and in cattle that are forced to walk or transported. Immobility is a prominent clinical finding and may be a protective mechanism so that adhesions are able to form and localize the peritonitis. Animals made to walk or transported long distances frequently suffer relapses when these adhesions are broken during body movements. Generalized peritonitis results in toxemia, alimentary tract stasis, dehydration and shock.

During the initial penetration of the reticulum, the foreign body may penetrate beyond the peritoneal cavity and into the pleural or pericardial sacs. This may occur more commonly in cows in advanced pregnancy than in nonpregnant cows, because of the gravid uterus, although this is uncertain. Complications such as pericarditis occur most commonly in cows after the sixth month of pregnancy.

Details of the pathogenesis of the more common complications are presented under traumatic pericarditis, vagus indigestion, diaphragmatic hernia and traumatic abscess of the spleen and liver. Less common sequelae include rupture of the left gastroepiploic artery causing sudden death due to internal hemorrhage and the development of a diaphragmatic abscess, which infiltrates tissues to the ventral abdominal wall at the xiphoid process, rupturing to the exterior and sometimes discharging the foreign body. Hematogenous spread of infection from a diaphragmatic abscess or infection from a diaphragmatic abscess of the pericardium causes pressure on the pericardial sac and congestive heart failure. Rarely, the foreign body penetrates to the abomasum, causing abomasitis, pyloric stenosis and abomasal ulceration. Even more rarely, puncture of the reticular vein by a migrating metal wire may lead to fatal hemorrhage causing sudden death.

**CLINICAL FINDINGS**

**Acute local peritonitis**
Characteristically, the onset is sudden with complete anorexia and a marked drop in milk yield, usually to about a third or less of the previous milking. These changes occur within a 12-hour period and their abrupt appearance is typical. Subacute abdominal pain is common in most cases. The animal is reluctant to move and does so slowly. Walking, particularly downhill, is often accompanied by grunting. Most animals prefer to remain standing for long periods and lie down with great care; habitual recumbency is characteristic in others.

**Arching of the back** occurs in about 50% of cases, along with the appearance of tenseness of the back and the abdominal muscles so that the animal appears gaunt or 'tucked-up'. **Defecation and urination cause pain** and the acts are performed infrequently and usually with grunting. This results in constipation, scant feces and in some cases retention of urine. Rarely, acute abdominal pain with kicking at the belly and stretching occurs. In others there is recumbency and reluctance to stand.

A moderate systemic reaction is common in acute localized peritonitis. The temperature ranges from 39.5–40°C (103–104°F), rarely higher, the heart rate is about 80/min and the respiratory rate about 30/min. Temperatures above 40°C (104°F) accompanied by heart rates greater than 90/min suggest severe complications. The respirations are usually shallow and, if the pleural cavity has been penetrated, are painful and accompanied by an audible expiratory grunt.

**Rumination is absent and reticulo-rumen movements are markedly depressed and usually absent. The rumen may appear to be full because of the presence of a free-gas bloat with moderate distension of the left paralumbar fossa.** On palpation of the fossa, the ruminal gas cap is usually larger than usual and the rumen contents more doughy than normal. Deep palpation of the gas cap in the fossa may be required to feel the rumen pack below the gas cap.

**Pain can be elicited by deep palpation of the abdominal wall just caudal to the xiphistemum.** Palpation is done using short, sharp pushes with the closed fist or knee over an imaginary band about 20 cm wide covering the ventral third of the abdomen from the left to the right side with the cranial border of the band being the point just caudal to
the xiphisternum. This area should be probed with at least six deep palpations on both sides of the abdomen while listening with a stethoscope over the trachea for evidence of a grunt. Pinching the withers to cause depression of the back and eliciting a grunt is also an effective diagnostic aid, except in large adult cows and bulls; for these the sharp elevation of a solid rail held horizontally under the abdomen is a useful method for eliciting a grunt. A positive response to any of these tests is a grunt of pain, which may be audible some distance away but is best detected by auscultation of the trachea. Rarely, a grunt may also be audible by auscultation over the trachea when infrequent reticulorumen contractions occur.

The course of acute local peritonitis is short and the findings described above are most obvious on the first day; in most cases they subside quickly and may be difficult to detect by the third day. In these cases, in addition to persistent anorexia and ruminal atony, the most constant finding is the abdominal pain, which may require deep palpation for its demonstration. In cases that recover spontaneously or respond satisfactorily to conservative treatment there may be no detectable signs of illness by the fourth day.

Chronic local peritonitis
In chronic peritonitis the appetite and milk yield do not return to normal after prolonged therapy with antimicrobials. The body condition is usually poor, the milk yield do not return to normal after the fourth day.

Rectal examination
Rectal examination of cattle with acute or local traumatic reticuloperitonitis may cause a painful grunt when the animal strains during the examination. The feces are usually dry and firm and covered by a thin coating of mucus because of prolonged retention. In acute localized peritonitis the rumen may feel larger than normal and the gas cap is easily palpable. In acute and chronic generalized peritonitis, fibrinous adhesions may be palpable between the rumen and the left abdominal wall or between loops of intestine, or in the pelvic cavity.

Acute diffuse (generalized) peritonitis
Acute diffuse peritonitis is characterized by the appearance of profound toxemia within a day or two of the onset of local peritonitis. Alimentary tract motility is reduced, mental depression is marked and the temperature is elevated or subnormal in severe cases, especially those that occur immediately after calving. The heart rate increases to 100–120/min and a painful grunt may be elicited by deep digital palpation at almost any location over the ventral abdominal wall. This stage is usually followed by rapid collapse and peripheral circulatory failure and an absence of pain responses. Terminally, recumbency and depression are common.

Sudden death
There is a record of sudden death in a 20-month-old pregnant heifer in which the reticular vein was punctured by a migrating piece of metal wire, causing fatal hemorrhage into the reticulum. At necropsy, a large blood clot was present in the reticulum, the rumen contents were red brown and no reticular adhesions were present.

iatrogenic reticulitis
There is a record of iatrogenic reticulitis that occurred as a result of the oral administration of intraruminal anthelmintic boluses, which may have lodged in the reticulum and become filled with other foreign objects ingested by the animal, resulting in a syndrome similar to acute traumatic reticuloperitonitis. Inappetence, reduced milk production, reduced reticulorumen motility, abdominal pain and scant feces were present. On exploratory rumenotomy the reticulum contained two cylindrical boluses filled with stones, nuts and bolts. Removal of the boluses was followed by prompt recovery.

CLINICAL PATHOLOGY
Hemogram
The total and differential leukocyte counts provide useful diagnostic and prognostic data. The differential leukocyte count is usually considerably more indicative of acute peritonitis than the total count.

In acute local peritonitis a neutrophilia (mature neutrophils above 400/μL) and a left shift (immature neutrophils above 200/μL) are common. This is a regenerative left shift. Both the neutrophilia and the left shift will be increased on the first day and will last for up to 3 days, when in uncomplicated cases the count begins to return to normal. In chronic cases the levels do not return completely to normal for several days or longer periods and there is usually a moderate leukocytosis, neutrophilia and a monocytosis.

In acute diffuse peritonitis a leukopenia (total count below 4000/μL) with a greater absolute number of immature neutrophils than mature neutrophils (degenerative left shift) occurs, which suggests an unfavorable prognosis if severe. The degree of lymphopenia (lymphocyte count below 2500–3000/μL) is an indication of a stress reaction to inflammation.

Plasma protein and fibrinogen
There is a significant difference in total plasma protein levels between cattle with traumatic reticuloperitonitis and those with other diseases of the gastrointestinal tract that might be confused with the former. The mean plasma protein concentrations, measured before surgery, were 88 ± 13 g/L for traumatic reticuloperitonitis and 77 ± 12 g/L for controls. In severe diffuse peritonitis the fibrinogen levels may be increased up to 10–20 g/L.

Cut-off points for total plasma protein (TPP) and plasma fibrinogen (PF) were determined to differentiate between traumatic reticuloperitonitis and other gastrointestinal diseases with similar clinical findings. There was moderate negative dependence between sensitivities of TPP and PF at the 8.82 g/dL and 766 mg/dL cut-off points, and mild negative dependence between their specificities at the 7.78 g/dL and 691 mg/dL cut-off points, respectively. Acceptable accuracy (98% or 86% specificity with 62% or 88% sensitivity, respectively) was obtained with serial interpretation of the tests.

Abdominocentesis and peritoneal fluid
Abdominocentesis and analysis of peritoneal fluid can be a valuable diagnostic aid. The best site for abdominocentesis is uncertain because the rumen occupies a large portion of the ventral abdominal wall and avoiding penetration of it is difficult. Cattle have a low volume of peritoneal fluid and failure to obtain a sample is not unusual. Empirically, the best sites are those in which, on an anatomical basis, there are recesses
between the forestomachs, abomasum, diaphragm and liver. These are usually 10–12 cm caudal to the xiphisternum and 10–15 cm lateral to the midline. A blunt-ended teat cannula is recommended but with care and caution a 16-gauge 5 cm hypodermic needle may also be used. The hair of the site is clipped, the skin is prepared aseptically and a local anesthetic is applied. The skin in incised with a stab scalpel and the cannula is pushed carefully and slowly through the abdominal wall. The latter will twitch and a ‘pop’ will be felt when the peritoneum is punctured. When the cannula is in the peritoneal cavity the fluid may leak out without the aid of a vacuum. If it does not, a syringe may be used to apply a vacuum while the needle is manipulated in an attempt to locate some fluid.

If no fluid can be obtained, a trocar and cannula 80 mm long and with a 4 mm internal diameter can be used with success. The trocar and cannula are inserted into the abdomen, the trocar is removed and an 80 cm long 10 French gauge infant feeding tube is inserted into the abdomen through the cannula, leaving about 10–20 cm outside. The tube acts as a wick and within several minutes fluid can be collected into vials. At least three different sites should be attempted to obtain peritoneal fluid. Peritonitis in cattle is characterized by a marked fibrinous response and localization of a lesion, and the amount of exudative fluid available at the abdominocentesis sites may be minimal. Thus the failure to obtain fluid does not preclude the presence of peritonitis.

Laboratory evaluation of peritoneal fluid consists of determinations of total white blood cell count, differential cell count, total protein and culture for pathogens. The interpretation of the analysis of the peritoneal fluid can be unreliable because to date only a few correlations have been made between the laboratory findings and the presence or absence of peritoneal lesions. A nucleated cell count above 6000 cells/μL and total protein above 3 g/dL is consistent with the diagnosis of peritonitis in 80% of cases. Using a differential cell count, a relative neutrophil count more than 40% and a relative eosinophil count less than 10% was frequently associated with the diagnosis of peritonitis.

**METAL DETECTION**

Metal detectors were used at one time to aid in the diagnosis of traumatic reticulo-peritonitis. Ferrous metallic foreign bodies can be detected with metal detectors but the instruments are of limited use because most normal dairy cows are positive for metal over the reticulicular area.

**LAPAROSCOPY**

Right flank laparoscopy using a flexible fiberoptic laparoscope, 14 mm diameter and 1120 mm working length, is a reliable diagnostic aid for the presence of traumatic reticulo-peritonitis.

**RADIOGRAPHY OF CRANIAL ABDOMEN AND RETICULUM**

Radiological examination of the reticulum with the animal in dorsal recumbency (dorsal reticulography) is an accurate diagnostic method for the evaluation of cattle with suspected traumatic reticulo-peritonitis. However, the lack of adequate radiographic equipment in private veterinary practices precludes its routine use. Also, the technical difficulties of positioning the animal and the increased potential for personnel exposure associated with manual restraint suggests that it may not be practical except for valuable animals that may warrant referral to a veterinary medical center.

The cranoventral abdomen of cattle can be evaluated using two cranial abdominal and one caudal thoracic radiographs. An X-ray machine with a capacity of 1000–1250 mAs and 150 kV is necessary, which is usually only available in veterinary teaching hospitals. However, such techniques may be inappropriate in valuable animals in which an accurate diagnosis and prognosis for surgical treatment may be desirable. In a consecutive series of standing cranial abdominal radiographs, the sensitivity and specificity for detecting traumatic reticulo-peritonitis or pericarditis was 83% and 90%, respectively. These values are higher than those achieved with dorsal recumbency. In standing lateral radiographs, an enlarged reticulum was associated with a final diagnosis of vagal indigestion. Alteration in reticulo-diaphragmatic separation does not correlate with any specific disease process. The presence of focal perireticular gas collections and reticular foreign bodies greater than 1 cm in length unattached to a magnet were good indicators of traumatic reticulo-peritonitis. Radiography is best suited for identification of radiodense foreign bodies in and outside the reticulum (these cannot be visualized ultrasonographically). Features found to be reliable in the diagnosis of traumatic reticulo-peritonitis using lateral radiographs of the reticulum include:

- Atypically positioned foreign bodies
- Abnormal gas shadows in the region of the reticulum
- Depressions in the cranoventral margin of the reticulum.

**ULTRASONOGRAPHY OF THE RETICULUM**

Ultrasonography is a suitable method for investigation of reticular contractions in healthy ruminants and in cattle for the diagnosis of traumatic reticulo-peritonitis. The literature on the use of ultrasonography as a diagnostic aid in gastrointestinal disease in cattle has been reviewed. The reader is referred to an excellent atlas and textbook on the use of ultrasonography in cattle.

The reticulum and adjacent organs of cows can be examined with ultrasonography using a 3.5 MHz linear transducer applied to the ventral midline of the thorax over the sixth and seventh intercostal spaces and from the left and right sides of the midline. It may not be possible to image the reticulum in large cows in good body condition because of the high proportion of fat in the muscle layers. In older cows, calcification of the xiphistemum may interfere with imaging. The most common reason for being unable to visualize the reticulum in sick animals is the displacement of the reticulum by a markedly distended rumen or by space-occupying lesions such as abscesses and fibrin-containing effusions. The pattern, number, amplitude and duration of the interval between contractions can be visualized. The contour of the reticulum, the reticular contractions and the organs adjacent to the reticulum can be imaged. The biphasic reticular contractions can be visualized at the rate of 4 during a 4-minute period. During the first incomplete contraction, the reticulum contracts by a mean of about 7.2 cm and during the second contraction the reticulum disappears from the screen.

**Ultrasonography for traumatic reticulo-peritonitis**

In contrast to radiography, ultrasonography provides more precise information about the contour of the reticulum and reticular motility. In cattle with traumatic reticulo-peritonitis, ultrasonography can be used to identify morphological changes in the region of the cranial, ventral or caudal reticular wall. The caudal ventral reticular wall is the most frequently affected, often in...
association with the craniodorsal blind sac of the rumen. The changes in the contour of the reticulum depend on the severity of the inflammatory changes.

The reticulum can be visualized in more than 90% of cows in spite of interference by the ribs and sternum. In cows with disturbed reticular motility, biphasic contractions are slower than normal, or indistinct, and the number of contractions is reduced. Fibrinous material appears as echogenic deposits, sometimes accompanied by hypoechochogenic fluid. Reticular abscesses have an echogenic capsule with a hypoechochogenic center. Involvement of the spleen, omasum, liver and abomasum may also be imaged. Neither magnets nor foreign bodies can be visualized by ultrasonography.22

Reticular activity is almost always affected in cattle with traumatic reticuloperitonitis. The frequency, amplitude or velocity of contractions, singly or combined, may be abnormal. The frequency can be reduced from 3 to 2, 1 or no contractions per 3 minutes. The reduction in the amplitude of contractions varies: when formation of adhesions is extensive, reticular contractions appear indistinct. Although the pattern of biphasic contraction is often maintained, the reticulum contracts only 1–3 cm. The velocity of reticular contractions may be normal but can be markedly reduced. In cattle with reticulo-omasal obstruction due to a foreign body, the frequency of reticular contractions may be increased.23

Reticular abscesses associated with traumatic reticuloperitonitis can be visualized by ultrasonography.6 (Fig. 6.5). The amplitude of reticular contractions is reduced, the reticulum is displaced from the ventral body wall, and the abscesses have hypoechochogenic centers and echogenic capsules.

Peritoneal effusion is visible as an accumulation of fluid without an echogenic margin and restricted to the reticular area. Depending on the fibrin and cell content, the fluid may be anechoic or hypoechochogenic. Fibrinous deposits are easily identified in the fluid and bands of fibrin are sometimes seen within the effusion. Occasionally, the peritoneal effusion is considerable and extends to the caudal abdomen.

The spleen, particularly its distal portion, is often affected. Fibrinous changes are frequently seen as echogenic deposits of varying thickness, often surrounded by fluid, between the spleen and reticulum or rumen. The spleen may be covered by fibrinous deposits. Occasionally, one or more splenic abscesses are visible, and the vasculature may be dilated, indicating splenitis.20

**Ultrasonography and radiography of cattle with traumatic reticuloperitonitis**

These two techniques have been compared in cows with traumatic reticuloperitonitis. The major advantages of radiography are that metallic foreign bodies can be visualized and their position determined. It has a specificity of 82%, a positive predictive value of 88% and a sensitivity of 71%.24 Abnormal gas shadows or gas–fluid interfaces observed on radiographs is an important finding for the diagnosis of traumatic reticuloperitonitis, with a specificity of 80% and a positive predictive value of 82%. Thick-walled changes or abscession should be suspected when the reticulum is displaced caudodorsally from the sternum. Changes in the contour of the reticulum such as indentations are highly suggestive of inflammation, with a specificity of 95% and positive predictive value but a low sensitivity of only 34%.

The major advantage of ultrasonography is being able to visualize and assess reticular motility.19,22,24 Even in the presence of severe adhesions and abscessation, the reticulum may maintain its basic contractile rhythm, but much reduced. Abscesses have an echogenic capsule of varying width and a central cavity filled with hypoechochogenic material. Purely fibrous deposits are echogenic, and fibrinous deposits containing an accumulation of fluid from inflammatory processes are echogenic interspersed with hypoechochogenic accumulations of fluid (Fig. 6.6).24 Radiography and ultrasonography complement each other and the combined results can be used to decide whether an exploratory laparotomy is indicated, if the animal should be treated conservatively with antibiotics, or if it should be slaughtered for salvage.22

**Necropsy findings**

Localized traumatic reticuloperitonitis is characterized by varying degrees of locally extensive fibrinous adhesions between the cranioventral aspects of the reticulum and the ventral abdominal wall and the diaphragm. Adhesions and multiple abscesses may extend to either side of the reticulum involving the spleen, omasum, liver, abomasum and ventral aspects of the rumen. Large quantities of turbid, foul-smelling peritoneal fluid may be present, containing fibrinous clots. Some cases of reticular abscesses are solitary and there are adhesions between the reticulum, diaphragm and ventral body wall, which are strictly localized. The size of the abscess varies. It may be from 5–10 cm in diameter or else a single one may be irregularly shaped and measure 30 × 10 × 10 cm, along with multiple smaller ones measuring around 3 × 3 × 3 cm.24 The foreign body can usually be found perforating the cranioventral aspect of the reticulum, although it may have fallen back into the reticulum, leaving only the perforation site and its surrounding...
In acute diffuse peritonitis a fibrinous or suppurative inflammation may affect almost the entire peritoneal cavity with extensive fibrinous adhesions of various stages of development involving the forestomach, abomasum, small and large intestines, liver, bladder, reproductive tract and pelvic cavity. Large quantities of turbid, foul-smelling fluid containing clots of fibrin are usually present. Loops of intestine and omenta are commonly stuck together by thick layers of fibrin.

**Differential Diagnosis**

Typical acute traumatic reticuloenteritis is characterized by a sudden onset of complete anorexia, marked drop in milk production, mild fever, ruminal atony, pain on deep palpation of the ventral abdomen, an elevated leukocyte count with a left shift in the hemogram and a peritoneal fluid sample that indicates inflammation. However, the times at which cases of traumatic reticuloenteritis are seen varies from day 1, when the syndrome is typical, to day 3 or 4, by which time the acuteness has subsided so much clinically that confusion with other diseases is a significant possibility. The sudden onset of anorexia and marked drop in milk production will usually be noted in lactating dairy cattle but not in dry dairy cattle or beef cattle, including mature bulls whose feed intake and behaviors are not monitored daily. In these animals the clinical findings can change in a few days and be characterized by anorexia to inappetence, normal temperature, ruminal hypotonicity or atony and no evidence of abdominal pain on deep palpation of the abdomen.

The clinician must review the history carefully, conduct a thorough clinical examination and attempt to intensify the diagnostic efforts on those abnormalities that are present. The differential diagnosis of gastrointestinal dysfunction of cattle is summarized in Table 6.2. An algorithm for the causes of grunting in cattle is shown in Fig. 6.7.

**Acute local traumatic reticuloenteritis**

Acute local traumatic reticuloenteritis must be differentiated from those diseases in which sudden anorexia, sudden drop in milk production, ruminal atony, abdominal pain and abnormal feces are common. They include the following:

- **Simple indigestion** characterized by sudden anorexia or inappetence, normal mental state, full rumen but atonic, perhaps uncomfortable if ingested large quantities of palatable feed like fresh silage, normal vital signs, abnormal feces and spontaneous recovery in 24 hours are typical

- **Obstruction of reticulo-omasal orifice** with a foreign body such as a roll of polyethylene twine causes intermittent inappetence, a slightly enlarged rumen with normal motility, slight reduction in the amount of feces, a decrease in milk yield for 24–48 hours followed by a return to normal and then subsequent relapses. A grunt is not present, the temperature, heart and respiratory rates are normal and the hemogram is normal. Obstruction of the reticulo-omasal orifice with foreign bodies such as rope can cause distension and hypermotility of the rumen and persistent vomiting.23 A rumenotomy must be done to make the diagnosis

- **Acute carbohydrate engorgement** characterized by sudden anorexia, diarrhea and dehydration, weakness, tachycardia, staggering, ruminal distension and atony, fluid-splashing sounds in the rumen with a rumen pH of less than 5 and a history of access to grain

- **Acute intestinal obstruction** characterized by sudden anorexia, mild abdominal pain perhaps with kicking at the abdomen and stretching, ruminal atony, mild dehydration, scant feces or complete absence of feces, straining on rectal examination, dark blood-stained feces and perhaps distended loops of intestine palpable on rectal examination

- **Abomasal volvulus (following right-side dilatation)** characterized by anorexia, dehydration, tachycardia, distended right abdomen, ping audible over right flank, distended vescic palpable on rectal examination. Usually in lactating dairy cows a few weeks after parturition and following the clinical findings of right-side dilatation of the abomasum that lasts several days culminating in the volvulus but may occur spontaneously in some cows with no immediate history of previous illness

- **Pericarditis.** Continued high fever, toxemia, anorexia, tachycardia and muffled heart sounds suggest pericarditis, which is marked by markedly elevated total leukocyte and neutrophil counts. In pericarditis, the heart sounds are muffled and the typical to and fro fluid-splashing sounds are audible. The jugular veins are engorged and other signs of congestive heart failure such as anasarca are present. Pericardiocentesis to obtain foul-smelling, turbid fluid is diagnostic

- **Acute pleuritis** is characterized by a fever, toxemia, anorexia, painful respirations that may be accompanied by a grunt, pain on digital palpation of intercostal spaces, ruminal atony, and abnormal and muffled lung sounds. Fluid on thoracentesis

- **Perforated abomasal ulcer** causes acute local peritonitis characterized by marked pain on palpation over a much larger area of the abdominal wall and in the early stages is most marked on the right-hand side. If, as is usual, the peritonitis becomes diffuse the syndrome cannot be distinguished
Acute diffuse peritonitis is characterized by anorexia, fever, tachycardia, dehydration, weakness leading to recumbency, distended abdomen, ruminal atony, spontaneous grunting or a grunt on deep palpation of abdomen, fluid-splashing sounds and pings on auscultation and percussion or ballottement of the abdomen due to ileus, scant feces, possibly palpable fibrinous adhesions on rectal palpation, profuse quantities of abnormal peritoneal fluid and marked changes in the hemogram. It must be differentiated from those diseases causing severe toxemia or combined with immobilization provided treatment is begun in the early stages of the disease. Cows past their sixth month of pregnancy are unlikely to recover completely and commonly relapse.

Rumenotomy
Surgical removal of the foreign body through a rumenotomy incision is widely used as a primary treatment. It has the advantage of being both a diagnostic procedure in the first instance and a satisfactory treatment. The recovery rate varies, depending on when the surgery is done relative to the time of initial penetration, but is approximately the same as that obtained with the conservative treatment described above. In both instances 80–90% of animals recover compared with about 60% in untreated animals. Failure to improve is usually due to involvement of other organs or to the development of locally extensive peritonitis and reticular abscesses associated with persistent penetration of the foreign body or, uncommonly, generalized peritonitis.

Based on follow-up ultrasonography of cows that had surgery for traumatic reticuloperitonitis, the inflammatory adhesions resolved and disappeared in the majority of animals by 6 months. As a consequence, reticular function normalizes. In animals with severe adhesions, there is a marked disturbance of digesta passage and, in these animals, extensive abscesses are present.

Persistent penetration by the foreign body necessitates removal for optimum results but a rumenotomy is necessary to determine the extent of the lesion. Radiography and ultrasonography as described above may assist in determining the presence and location of the foreign body. A single preoperative dose of antimicrobial such as potassium penicillin G at 10 million IU given intravenously is recommended to avoid complications after a rumenotomy in cattle.

The recovery rate after surgery is likely to be much lower if only complicated cases are selected for rumenotomy and conservative treatment is given to the early mild cases. In one series the recovery rate in the cases treated conservatively was 84% and in those difficult cases treated surgically it was 47%.

Drainage of reticular abscesses
Reticular abscesses may be drained through an ultrasound-guided transcutaneous incision.

Choice of treatment
The choice of treatment is largely governed by economics and the facilities and time available for surgery. A rumenotomy, satisfactorily performed, is the best treatment but is unnecessary in many cases because of the tendency of...
Fig. 6.7 Causes of grunting in cattle.

The foreign body was accidentally ingested as part of the feed and a high rate of accident is seen in the initial months of pregnancy. In the early stages of the disease, movement of the cow during the last 3 months of pregnancy if severe sequelae are to be avoided. Movement of the cow during the early stages of the disease is undesirable because of the risk of disrupting the adhesions that localize the infection.

Cases of chronic traumatic reticulo-peritonitis are best treated by rumenotomy and if marked improvement has not occurred by that time to consider a peritonectomy. As the foreign body is still embedded in the wall. Acute diffuse peritonitis is highly fatal but if detected early daily treatment with broad-spectrum antimicrobials may be effective.

PREVENTION

All processed feed should be passed over magnets to remove metallic material before being fed to cattle. The use of synthetic string instead of wire has resulted in a major decrease in the incidence of the disease.

Reticular magnets

Small cylindrical or bar magnets, 7.5 cm long by 1.0–2.5 cm diameter with rounded ends, are used to prevent the disease but are also used in acute cases to minimize penetration of the foreign body. When given orally to normal healthy animals the magnets locate in the reticulum within a few days, where they remain indefinitely and maintain their magnetic pull. The magnets attract foreign bodies, which then do not penetrate the reticular wall as easily as when they are free. The extensive prophylactic use of these magnets in a dairy herd has reduced the incidence of the disease and its complications by 90–98%. The magnets are given to herd replacement heifers at 18 months to 2 years of age as part of a herd health program.

The effects of magnets in traumatic reticulitis was examined in the Danish study of cows at slaughter (see under Etiology). Two magnets tested were cylindrical cage magnets with different fields of magnetic force. Magnet I had a magnetic force of attraction of 110 mT; magnet II had a force of 210 mT. Magnets were found in only 7% of the cows. There were no lesions in 97% of the cows with magnets. Magnet II was superior to magnet I in attracting all types of foreign bodies, including tire wires. Thus the prophylactic use of magnets should be promoted to reduce the occurrence of foreign body lesions.

It is unlikely that magnets will extract a firmly embedded foreign body from the wall of the reticulum but loosely embedded ones with long free ends may be returned to the reticulum and loose foreign bodies will be immobilized. The position of the foreign body within the reticulum greatly influences the efficacy of treatment with a magnet. A foreign body at an angle to the ventral aspect of the reticulum of more than 30° is less likely to become attached to a magnet than a foreign body situated horizontally on the ventral aspect of the reticulum. There have been only a few reports of physical injury to the wall of the reticulum being caused by the magnets or the foreign bodies that may be attached to them. A compass can be used to locate the presence and position of the magnet.

REFERENCES

The prevailing explanation was that dorsal vagal nerve injury resulted in achalasia of the reticulo-omasal orifice (anterior stenosis) and inhibited the passage of ingesta from the reticulo-rumen into the omasum and abomasum, resulting in an enlarged rumen with abnormal rumen contents. Similarly, injury of the pyloric branch of the ventral vagus nerve resulted in achalasia of the pylorus (posterior stenosis) and inhibited the flow of ingesta from the abomasum resulting in abomasal impaction. Both abnormalities resulted in scant feces containing undigested long feed particles.

However, while in many cases of vagus indigestion there are extensive adhesions between the reticulum and adjacent organs, there is little evidence of vagal nerve injury. It is also known that the syndrome can occur without any gross evidence of inflammation of the serosa of the forestomach and abomasum over which the vagus nerves are located. In the absence of gross lesions, it has been suggested that microscopic lesions of the medial reticular wall where vagal tension receptors are located may interfere with forestomach motility and esophageal groove reflexes.

New information based on clinical-pathological examination of clinical cases has questioned the long-held view that vagal nerve injury is an important cause of this syndrome.

Reticular adhesions
Mechanical impairment of reticular motility and esophageal groove dysfunction as a result of reticular adhesions is probably the most important cause of the syndrome. An examination of 42 dairy cows with complications of traumatic reticuloperitonitis found that the primary mechanism was a disturbance in particle-separation processes in the reticulo-rumen attributable to mechanical inhibition of reticular motility associated with extensive inflammatory para-recticular adhesions. Based on examination of necropsy tissue grossly and histologically, there was no evidence of vagal nerve injury. Perireticular abscesses near the reticulo-omasal orifice of cattle can cause the disease,\(^1\)

Other causes
Several causes unrelated to traumatic reticuloperitonitis have been recorded. Actinobacillosis of the rumen and reticulum is a less common cause. In sheep, peritonitis associated with Saccharibactria and Cysticercus tenuicollis may be a cause. Fibropapillomas of the cardia can mechanically occlude the distal esophagus and cause interference with forestomach motility.\(^3\) Abomasal impaction in sheep has been recorded but the etiology and pathogenesis have not been determined. Disturbances similar to those that occur under natural conditions have been produced by sectioning the vagus nerve. Following surgery for right-sided abomasal displacement or volvulus, some cattle develop a vagus-indigestion-like syndrome characterized by anorexia, scant feces, ruminal distension and abdominal distension. It has been suggested that distension of the abomasum and thrombosis of its vessels may have caused injury to the ventral vagus nerve.\(^4\)

Pyloric achalasia is described as part of a secondary indigestion due to septicemia and toxemia but this is not well documented. There is also ruminal distension with fluid material, abomasal reflux into the reticularum, dehydration, hypochloremia, hypokalemic metabolic alkalosis and uremia.

Indigestion of late pregnancy of cows is considered a type of vagus indigestion in which the rumen and abomasum are grossly distended, but the cause is uncertain.\(^5\) There is no evidence that the effects of an advanced pregnancy alone will cause a vagus-indigestion-like syndrome.

Peripheral nerve sheath tumors, such as a solitary schwannoma have been described causing a syndrome similar to vagus indigestion in a mature cow.\(^6\) A vagal indigestion-like syndrome may be a post-surgical complication of right abomasal displacement. Gastric wall injury, peritonitis and vagal nerve lesions may be causative factors. It occurs in 14–21% of cases, and only 12–20% of cases return to normal production. (See under Right-side displacement of the abomasum and abomasal volvulus.)

**Etiology**
The etiology has been controversial but has been divided into two major subcategories of complications of traumatic reticuloperitonitis: vagal nerve injury and reticular adhesions. In addition there are some other causes.

**Complications of traumatic reticuloperitonitis**
Vagal nerve injury and dysfunction Historically, it was thought that vagus indigestion was caused by vagal nerve dysfunction due to vagal nerve injury associated with complications of traumatic reticuloperitonitis. It was hypothesized that the inflammatory and scar tissue lesions affected vagal nerve fibers supplying the forestomach and abomasum. The naturally occurring syndrome was similar to the Hoflund syndrome created by experimentally sectioning the vagus nerves and thus the term ‘vagus indigestion’ was coined.

**ETIOLOGY**
The syndrome occurs most commonly in dairy cows that have a history of traumatic reticuloperitonitis, which may have occurred several weeks or a few months previously. The disease is not restricted to dairy cows – it also occurs in beef cattle and in mature bulls.

**Pathogenesis**
The syndrome of vagus indigestion is characterized by disturbances in the passage of ingesta through the reticulo-omasal orifice (failure of omasal transport, anterior functional stenosis) and disturbances in the passage of ingesta through the pylorus (pyloric stenosis, posterior functional stenosis). Stenosis is a misnomer because there is no evidence of stenosis but achalasia of the sphincters may occur. The characteristic clinical findings are distension of the rumen with pasty and/or frothy contents because of increased time and maceration in the reticulorumen, alterations in reticulorumen and omasal contents.
reticulorumen motility, with consequences such as dehydration, an increase in undigested particles in the feces, scant feces, acid-base imbalance and secondary starvation. It is an outflow abnormality of the reticulorumen and abomasum.

Based on careful clinicopathological observations of 42 cows with complications of traumatic reticuloperitonitis including "vagus indigestion", it is now proposed that the disturbances in the flow of ingesta are associated with particle-separation in the reticulorumen caused by mechanical inhibition of reticulorumen motility associated with extensive adhesions of the reticulum. Experimentally impaired reticulorumen motility in sheep support the central role of reticulorumen motility for the separation of particles in the forestomach, the outflow of digesta from the reticulorumen and transpyloric digesta flow.8

Normally, reticulorumen motility results in stratification of ruminal contents into three layers of ingesta in addition to the most dorsal gas pocket. The top layer, consisting of firm fibrous material of low-density particles (coarse hay), floats on the middle layer of liquid ingesta, consisting of particles of medium density; the bottom layer consists of fine particles of high density. The solid material remains in the rumen and is digested until the particle size is sufficiently small (1–4 mm in cattle) to pass through the reticulo-omasal orifice. The size of the digested plant fragments in ruminant feces can be considered an indirect measurement of forestomach function. In cows, the presence of large plant particles (> 0.5 cm) in the feces indicates inadequate rumination or abnormalities in forestomach motility.7

In normal cattle, the mean retention time of particles in the reticulorumen depends on particle size and density: The density of large feed particles is low because of their air-filled interior. During biphasic reticulorumen contractions, most of these large, light particles are pushed caudodorsally in the rumen. Thus, large particles are retained in the reticulorumen, because outflow through the reticulo-omasal orifice occurs mainly during the maximum portion of the second reticulorumen contraction. Feed particles with a high density (small and well digested) are moved out of the reticulorumen preferentially, because the majority of them remain in the reticulum during the biphasic contraction.

If reticulorumen motility is inhibited, the balance of particle retention time and particle outflow in the reticulorumen is disturbed. Immobilization of the reticulum experimentally causes a decrease in feed intake, an increase in ruminal volume, a decrease of mean retention time of light plastic particles, a four-fold increase in mean retention time of heavy plastic particles, a marked increase in the amount of large particles in the feces, and an increase in abomasal volume. Such changes reflect the changes occurring in naturally occurring vagus indigestion. An increase in the amount of large particles in the feces of cows with traumatic reticuloperitonitis is indicative of inhibited clearance function of the reticulum.

Liquid consistency of the abomasal contents is important to insure physiological transpyloric flow. In cows with uncomplicated traumatic reticuloperitonitis, the process of particle separation in the reticulorumen is disturbed, which results in an increase in the amount of large particles in the feces. In uncomplicated traumatic reticuloperitonitis, the reticulorumen is not large and the abomasum is not impacted because the fluid outflow is probably adequate to flush even large particles out of the abomasum.

In cows with pyloric stenosis and an increase in the size of the abomasum, the rumen contents are homogeneous and pasty and not stratified. Thus, consistency of rumen outflow contents changes markedly. Normally, transpyloric digesta flow depends predominantly on hydrodynamic factors, especially viscosity. Even small increases in viscosity of abomasal contents may cause a marked decrease in abomasal outflow.

Disturbances of the passage of digesta in cows with traumatic reticuloperitonitis develop in three phases.

- **In the first phase**, reticulorumen motility is decreased because of immobilization of the reticulum caused by the inflammation, pain and fever. Immobilization of the reticulum impairs clearance function of the reticulum, resulting in poorly comminuted feces.
- **The second phase** occurs when the adhesions are extensive enough to cause additional impairment of reticular motility. Particle distribution within the reticulorumen is changed, resulting in a loss of stratification. Although feed intake decreases, the volume of the reticulorumen increases because rumen outflow is decreased. During the second phase, comparatively small amounts of rumen outflow contents can exit the abomasum, because the dry-matter content of the material is similar to that of a clinically normal cow. During this phase, the rumen may become hypermotile because of excitation of low-threshold tension receptors as a consequence of moderate rumen distention.
- **The third phase** is characterized by a further change in the consistency of rumen contents, resulting in a homogeneous paste of mass relatively high viscosity. The increase in dry-matter content of the rumen outflow material inhibits transpyloric digesta flow. The abomasum enlarges, and reflux of abomasal contents may occur. It is suggested that the primary underlying process of reflux of abomasal contents in cows with posterior stenosis is a disturbance of ruminal outflow.1

In summary, the current hypothesis for the pathogenesis indicates that disturbances of the passage of ingesta consists of two phases of the same syndrome. Pyloric stenosis represents the phase with the most severe clinical consequences. The prognosis is poorer for cows with anterior stenosis than for those with uncomplicated traumatic reticuloperitonitis and is poorer for cows with posterior stenosis than for those with anterior stenosis. Only a small percentage of cows with traumatic reticuloperitonitis develop disturbances of digesta passage through the reticulo-omasal orifice and not all cows with anterior stenosis develop posterior stenosis. The extent and location may determine the course of the syndrome and how rapidly it develops. In cows with acute traumatic reticuloperitonitis the consistency of the adheres changes from a widespread fibrous type to a stringy type after several months, and with time the reticulum may regain sufficient motility to provide its clearance function.

**Anterior functional stenosis** (achalasia)

This is characterized by accumulation of ingesta in the reticulorumen, known also as failure of omasal transport. If the ruminal wall is atonic the ingesta accumulates without bloat occurring; if it has normal motility the ruminal wall responds to the distension by increased motility and the production of frothy bloat. Ruminal motility will be almost continuous (3–6/min) but the contractions are ineffective in propelling the ingesta into the omasum. As a result the rumen enlarges to fill the majority of the abdomen, which accounts for the gross distension of the abdomen. The dorsal sac of the rumen enlarges to the right of the midline, and the ventral sac enlarges to fill most or all of the right lower quadrant of the abdomen; this results in the 'L-shaped' rumen as viewed from the rear of the animal. The continuous rumen contractions also result in frothy rumen contents, which can be fatal if progressive and not relieved. Occasionally there is free gas
bloat. Bradycardia occurs commonly and has been attributed to increased vagal tone of the injured nerve, causing parasympathetic slowing of the heart, but this has not been documented.

Obstruction of the reticulo-omasal orifice by foreign bodies such as polyethylene twine ingested by the animal may cause a syndrome indistinguishable from anterior functional stenosis.  

Posterior functional stenosis

This is characterized by failure of transpulic flow resulting in abomasal impaction with large particles. Abomasal fluid containing hydrochloric acid may reflux into the rumen if the fluid does not move from the abomasum into the small intestines. This is known as the abomasal reflux syndrome. The chloride concentrations in the rumen fluid increase and there is a hypochloremia and hypokalemia. Bile acids may also reflux from the duodenum into the rumen of animals with an ileus of the small intestine. Associated with pyloric achalasia is in some cases an apparent failure of the esophageal groove to permit the passage of ingesta into the rumen, this organ containing only fluid. The syndrome observed depends on the stage of the disease at which the animal is first examined.

Metabolic alkalosis, abomasal reflux

Depending on the location and severity of the functional obstruction and distension or impaction, there will be varying degrees of dehydration and a tendency towards a metabolic hypochloremic, hypokalemic alkalosis. In pyloric stenosis with abomasal impaction there is sequestration of abomasal fluid in the abomasum and a reflux of abomasal contents into the rumen, resulting in a ruminal chloride concentration of more than 20 mmol/L. In anterior stenosis, the abomasal fluid can pass into the duodenum and neither metabolic alkalosis nor dehydration can be expected.

Postsurgical complication in right-side displacement of the abomasum or abomasal volvulus

A vagus-indigestion-like syndrome may occur in cattle treated for right-side displacement of the abomasum or abomasal volvulus. Possible mechanisms include vagus nerve injury, overstretching of the abomasal wall during prolonged distension resulting in neuromuscular junction alterations and autonomic motility modification, thrombosis and abomasal wall necrosis, and peritonitis.

Abomasal impaction in sheep

Abomasal emptying defects associated with dilatation and impaction of the abomasum in Suffolk sheep have been reported. The electrolyte imbalances that occur in cattle with abomasal impaction do not occur in sheep.

CLINICAL FINDINGS

Three similar but separate clinical syndromes have been recognized, with some clinical findings characteristic of all three, including:

- Inappetence for several days or complete anorexia with evidence of loss of body weight
- An enlarged ‘papule’-shaped abdomen (pear-shaped on the right and apple-shaped on the left) with or without bloat. The upper left abdomen is distended and the lower half of the abdomen is distended bilaterally
- Dehydration and electrolyte imbalance with metabolic alkalosis
- Enlarged rumen palpable on rectal examination
- Scant feces with an increase in undigested particles
- Enlarged ingesta-impacted or fluid-distended abomasum palpable through right flank or on rectal examination (except cannot be easily palpated in advanced pregnancy)
- Vital signs within the normal range
- Inadequate response to treatment.

Ruminal distension with hypermotility

The occurrence of this type is not particularly related to pregnancy or parturition. Moderate to severe bloat is common. There is evidence of loss of body weight. The animal has usually been inappetent or anorexic intermittently for the past few weeks. The abdomen is prominently distended and the rumen movements represented by the abdominal ripples are often unusually prominent and may occur at the rate of 4-6 per minute. The sounds of the rumen contractions are often reduced or almost absent in spite of hyperactivity because the rumen contents are pasty and frothy. Initially, this contradiction is misleading because the hyperactivity of the rumen tends to indicate normal reticulorumen activity. Fluid-splashing sounds may also be audible on ballottement of the left and right flanks if the rumen is distended with excessive quantities of fluid. The temperature and heart rate are usually normal. There is no pain on deep palpation of the ventral abdomen. On rectal examination the primary abnormality is gross distension of the rumen, which may almost block the pelvic inlet. The animal loses weight rapidly, becoming weak and recumbent. At this stage the heart rate increases markedly. The animal dies slowly of inanition.

Pyloric obstruction and abomasal impaction

Most cases of abomasal impaction also occur late in pregnancy and are manifested by anorexia and a reduced volume of putty feces. There may be no abdominal distention and no systemic reaction until the late stages, when the heart rate rises rapidly. The distended and impacted abomasum may be palpable in the lower right abdomen as a heavy, doughy viscus. On rectal examination the impacted abomasum may be palpable as a doughy viscus that fits on pressure in the right lower quadrant. If the animal is in advanced pregnancy the impacted abomasum may not be palpable through the...
abdominal wall or by rectal palpation but the gravid uterus may feel as if it is displaced into the pelvic cavity by the enlarged abomasum. Rumen movements are usually completely absent. As in the first type, affected animals usually become weak and recumbent and die slowly of inanition and electrolyte and acid-base imbalances. In some cases, the impacted abomasum may rupture and cause death in a few hours.

Combinations of these types may occur; in particular, distension of the rumen with atony combined with abomasal impaction is the most commonly observed syndrome.

Indigestion of late pregnancy in cattle characterized by distension and hypomotility of the rumen with distension of the abomasum has been described but is probably not due to advanced pregnancy alone. In late pregnancy, the abomasum is difficult to examine clinically either through the abdominal wall or by rectal examination. The presence of fluid-splashing sounds on ballottement and auscultation over the right lower flank is indirect evidence of distension of the abomasum with fluid. The distended abomasum can be palpated and evaluated by left or right side laparotomy (celiotomy).

CLINICAL PATHOLOGY

Hemogram

In most cases there are no abnormalities on hematological examination although a moderate neutrophilia, a shift to the left and a relative monocytosis may suggest the presence of chronic traumatic reticuloperitonitis. Hemoconcentration is common, associated with the clinical dehydration. Total plasma protein concentrations may be increased, similar to traumatic reticuloperitonitis.

Peritoneal fluid

This may be indicative of a chronic reticuloperitonitis.

Serum biochemistry

In abomasal impaction there is metabolic hypochloremic, hypokalemic alkalosis.

Ruminal chloride concentrations

These are normally below 30 mmol/L and increased in posterior stenosis to levels above 40 mmol/L due to abomasal reflux. Levels of 66 mmol/L have been recorded in cows with indigestion of late pregnancy.

NECROPSY FINDINGS

The rumen is grossly enlarged and the contents are pasty and may be frothy. The contents may have undergone some putrefaction. In some cases the rumen is grossly distended with liquid rumen contents containing floating large particles of ingesta. The reticulum and omasum are usually grossly enlarged and the reticul-omosal orifice is commonly dilated and filled with rumen contents. The omasum may be almost twice its normal size and is firmer than normal. Sectioning of the orifice reveals rumen contents impacted between its leaves. The abomasum may be up to twice its normal size and firm on palpation. The abomasum is impacted and grossly distended with semi-dry partially digested ingesta that resembles partially dried rumen contents. Erosions and ulcers may be present in the pyloric part of the abomasum. The intestines may be relatively empty and the feces in the large intestine are pasty, containing an increased amount of undigested particles.

Lesions between the reticulum and ventral abdominal floor and the diaphragm vary considerably from thick fibrinous suppurative adhesions to multiple abscesses containing a foreign body or non-inflammatory fibrous bands and strings.

DIFFERENTIAL DIAGNOSIS

The salient clinical features of vagus indigestion in cattle are inappetence for several days leading to anorexia, a gradually enlarging abdomen, especially on the left side, scant feces, failure to respond to common medical therapy, loss of body condition and varying degrees of dehydration. Obtaining an accurate history is of paramount importance. Most cases of vagus indigestion have been affected for at least several days or a few weeks. The diagnosis can be perplexing in those cases that occur in late pregnancy because the animal has usually been housed and fed with other dry cows and daily observation of feed intake and fecal output have not been made, so it is difficult to obtain an accurate and helpful history. The clinical examination should focus on the state of the rumen and the abomasum. In valuable animals a left-side exploratory laparotomy and rumenotomy will often be necessary in order to make a diagnosis. This will allow the determination of the presence of reticular adhesions, obstructions of the reticulo-omasal orifice and the state of the abomasum.

The various forms of vagus indigestion must be differentiated from diseases of the forestomach and abomasum resulting in distension and hypermotility or atony of the rumen and enlargement of the abomasum.

• **Ruminal distension with hypermotility** is typical of vagus indigestion and, if accompanied by anorexia, dehydration, scant and abnormal feces, and a large L-shaped rumen on rectal examination, it must be differentiated from:
  - **Indigestion of late pregnancy**, characterized by anorexia, lethargy, dehydration, grossly distended papule-shaped abdomen, ruminal distension with hypermotility, abomasal distension with fluid, elevated ruminal chloride levels and hypochloremic, hypokalemic alkalosis.
  - **Omasal impaction** occurs sporadically and commonly part of the vagus indigestion syndrome but its cause is uncertain. Anorexia, ruminal distension and atony, scant inadequately digested feces.
TREATMENT
The prognosis in most cases is unfavorable but also unpredictable. The problem is to determine the location and extent of the lesion, which may be difficult or impossible even on exploratory laparotomy or rumenotomy.

Rumen lavage
If the rumen is grossly distended with fluid or mushy rumen contents, it can be emptied using a large-bore (25 mm inside diameter) stomach tube followed by flushing warm water into the rumen and lavaging it by gravity flow. The contents are usually well macerated and foul-smelling. Emptying the rumen not only relieves the pressure but allows for easier examination of the abdomen.

Fluid and electrolyte therapy and laxatives
Some cases respond beneficially following fluid and balanced electrolyte therapy for 3 days combined with the oral administration of mineral oil (5–10 L) daily for 3 days or dextrose sodium sulphocitrate as described under the treatment of abomasal impaction of dietary origin. Other cases do not respond but there is no reliable method of knowing which ones will respond rather than by attempting treatment for a few days. Valuable pregnant cows near parturition may be maintained on fluid and electrolyte therapy for several days or until near enough to term to induce parturition and hopefully obtain a live calf. Some cows will recover following parturition but the syndrome may recur in the next pregnancy.

Rumenotomy
Rumenotomy and emptying of the rumen is usually followed by slow recovery over a period of 7–10 days when there is ruminal hypermotility. The creation of a permanent ruminal fistula to permit the escape of gas in cases where gas retention is a problem may cause dramatic improvement. Surgical correction of abomasal distension or impaction by abomassotomy is usually unsatisfactory because the motility of the abomasum does not return. Surgical drainage of perireticular abscesses into the reticulum or omasum at the site of the lesion through a rumenotomy incision has been successful in prolonging survival of affected cattle for at least 1 year. Reticular abscesses may be drained successfully by ultrasound-guided transthoracic incision.

For some cases of vagus indigestion, the most satisfactory procedure may be to recommend slaughter for salvage. In suspected cases of obstruction of the reticulo-omasal orifice by rope or twine, an exploratory rumenotomy is required to remove the foreign object.

PREVENTION
This is dependent on preventing traumatic reticuloperitonitis through management of the environment and the administration of reticular magnets.

REFERENCES

DIAPHRAGMATIC HERNIA
Herniation of a portion of the reticulum through a diaphragmatic rupture causes chronic ruminal tympany, anorexia and displacement of the heart.

ETIOLOGY
Most cases occur because of weakening of the diaphragm by lesions of traumatic reticuloperitonitis, but diaphragmatic rupture can occur independently of a foreign body and congenital defects of the diaphragm may be a cause in some animals. An unusually high incidence of herniation of the reticulum through the diaphragm, sometimes accompanied by the abomasum, has been recorded in buffalo in India.

PATHOGENESIS
The usual syndrome is similar to that of vagus indigestion in which ruminal hypermotility is present. It seems probable that there is either achalasia of the reticulo-omasal sphincter due to involvement of the vagus nerve or impairment of function of the esophageal groove caused by the fixation of the reticulum to the ventral diaphragm. The disturbance of function in the forestomachs suggests that food can get into the rumen but cannot pass from there to the abomasum. The hypermotility is thought to be due to overdistension of the rumen and to be the cause of the frothy bloat.

There is usually no interference with respiration without major herniation but displacement and compression of the heart occur commonly.

CLINICAL FINDINGS
There is a capricious appetite and loss of condition for several weeks before abdominal distension due to accumulation of fluid and froth in the rumen, persistent moderate tympany of the rumen, occurs. Grinding of the teeth may occur and the feces are pasty and reduced in volume. Ruminination does not occur but occasionally animals regurgitate when a stomach tube is passed.

The temperature is normal and bradycardia may be present (40–60/min). Breathing is usually normal. A systolic murmur may be present and the intensity of the heart sounds may suggest displacement of the heart, usually anteriorly or to the left. Reticular sounds are audible just posterior to the cardiac area in many normal cows and they are not significantly increased in diaphragmatic hernia.

A more severe syndrome is recorded in cases where viscera other than a portion of the reticulum is herniated. Peristaltic sounds may be audible in the thorax and there may be interference with respiration and signs of pain with each reticular contraction. Affected animals usually die from inanition in 3–4 weeks after the onset of bloat.
CLINICAL PATHOLOGY
Laboratory examinations are of no value in diagnosis. Radiological examination after a barium meal has facilitated diagnosis.

NECROPSY FINDINGS
The majority of cases are complications of traumatic reticuloenteritis and a fistulous tract is often found in the vicinity of the diaphragmatic rupture which is usually 15-20 cm in diameter. A portion of the reticulum protrudes into the right pleural cavity to form a spherical distension usually 20-30 cm in diameter, but more extensive in some cases. The reticulum is very tightly adherent to the hernial ring which is thickened by fibrous tissue. The omasum and abomasum are relatively empty but the rumen is overfilled with frothy, porridge-like material which contains very little fiber. Less common cases are those in which part of the reticulum, the omasum and part of the abomasum are herniated.

DIFFERENTIAL DIAGNOSIS
- Other causes of chronic bloat must be considered in the differential diagnosis, especially vagus indigestion with hypermotility, which is also often accompanied by a systolic murmur. The two can only be differentiated by rumenotomy but there is the hazard that cases of diaphragmatic hernia are not relieved by the operation and tympany returns rapidly, sometimes necessitating a permanent ruminal fistula
- Passage of a stomach tube is usually necessary to determine whether or not a physical obstruction is present in the esophagus. Regurgitation is likely to occur in cases of diaphragmatic hernia and this occasionally causes blockage of the esophagus with ingesta, simulating choke
- Causes of diaphragmatic hernia other than traumatic reticuloenteritis include violent trauma to the abdomen and straining at parturition. In both instances there is probably a primary weakness of the diaphragm. In buffalo this is thought to be an anatomical characteristic of the species, the weakness being located in the right half of the diaphragm

TREATMENT
Most recorded attempts at surgical repair in cattle have been unsuccessful and treatment has not usually been recommended. The animals could not be left as they were, so salvage by slaughter has been the usual outcome.

The ruminal contents are frothy, and trocarization or passing a stomach tube has virtually no effect in reducing the tympany, nor have standard antifrothing agents. The tympany is usually not sufficiently severe to require emergency rumenotomy. The signs may be partly relieved by keeping the animal confined with the forequarters elevated.

TRAUMATIC PERICARDITIS
Perforation of the pericardial sac by a sharp foreign body originating in the reticulum causes pericarditis with the development of toxemia and congestive heart failure. Tachycardia, fever, engorgement of the jugular veins, anasarca, hydrothorax and ascites, and abnormalities of the heart sounds are the diagnostic features of the disease.

ETIOLOGY
Perforation of pericardial sac by foreign body originating from the reticulum

EPIDEMIOLOGY
Usually mature cattle; may have had history of traumatic reticuloenteritis

SIGNS
Depression, toxemia, fever, inappetence to anorexia, engorged jugular veins, brisket edema, heart sounds muffled and accompanied by pericardial friction rubs and to-and-fro fluid movement sounds

CLINICAL PATHOLOGY
Marked neutrophilia. Pericardiocentesis yields foul-smelling turbid fluid

LESIONS
Distension of pericardial sac, foul-smelling, grayish fluid containing fibrin. Adhesions and sinus tracts to reticulum

DIAGNOSTIC CONFIRMATION
Pericardiocentesis

DIFFERENTIAL DIAGNOSIS
Common causes of congestive heart failure in cattle include endocarditis, myocardiopathy (lymphomatosis), congenital cardiac defect

TREATMENT
Antimicrobials. Prognosis unfavorable. Euthanasia commonly recommended

CLINICAL FINDINGS
Depression, anorexia, habitual recumbency and rapid weight loss are common. Diarrhea or scant feces may be present and grinding of the teeth, salivation and nasal discharge are occasionally observed. The animal stands with the back arched and the elbows abducted. Respiratory movements are more obvious, being mainly abdominal, shallow, increased in rate to 40-50/min and often accompanied by grunting. Engorgement of the jugular veins, and edema of the brisket and ventral abdominal wall are common and in severe cases there may even be edema of the conjunctiva with grape-like masses of edematous conjunctiva hanging over the eyelids. A prominent jugular venous pulse is usually visible and extends proximally up the neck.

Pyrexia (40-41°C, 104-106°F) is common in the early stages and an increase in the heart rate to 100/min and a diminution in the pulse amplitude are constant. Ruminal movements are usually present but depressed. Pinching of the withers to
Depress the back or deep palpation of the ventral abdominal wall behind the xiphoid sternum commonly elicits a marked painful grunt. A grunt and an increased area of cardiac dullness can also be detected by percussion over the precordial area, preferably with a pleximeter and hammer.

Auscultation of the thorax reveals the diagnostic findings. In the early stages before effusion commences, the heart sounds are normal but are accompanied by a pericardial friction rub, which may wax and wane with respiratory movements. Care must be taken to differentiate this from a pleural friction rub due to inflammation of the mediastinum. In this case the rub is much louder and the heart rate will not be so high. Several days later when there is marked effusion, the heart sounds are muffled and there may be gurgling, splashing or tinkling sounds. In all cases of suspected pericarditis, careful auscultation of the entire precordium on both sides of the thorax is essential as abnormal sounds may be audible only over restricted areas. This is especially so in chronic cases.

Most affected animals die within a period of 1–2 weeks, although a small proportion persist with chronic pericarditis. The obvious clinical findings in the terminal stages are gross edema, dyspnea, severe watery diarrhea, depression, recumbency and complete anorexia. Enlargement of the liver may be detectable by palpation behind the upper part of the right costal arch in the cranial part of the right paralumbar fossa. Death is usually due to asphyxia and toxemia.

Animals which have recovered from an initial pericarditis are usually affected by the chronic form of the disease. Body condition is poor, the appetite is variable, there is no systemic reaction and the demeanor is bright. Edema of the brisket is usually not prominent but there is jugular engorgement. Auscultation reveals variable findings. The heart sounds are muffled and fluid splashing sounds may be heard over small discrete areas corresponding to the loculi of fluid in the sac, or there may be irregularity of the heart beat. The heart rate is rapid (90–100/min) and the pulse is small in amplitude. These animals remain unthriftily and are unlikely to withstand the stress of another pregnancy or lactation.

**Clinical Pathology**

*Hematogram*

A pronounced leukocytosis with a total count of 16 000–30 000/μL accompanied by a neutrophilia and eosinopenia is usual although less dramatic changes are recorded in one series of cases.

**Pericardiocentesis**

When gross effusion is present the pericardial fluid may be sampled by centesis with a 10 cm 18-gauge needle over the site of maximum audibility of the heart sound, usually in the fourth or fifth intercostal space on the left side. In mid-stage pericarditis the fluid is usually easily obtained, and is foul-smelling and turbid, which is diagnostic for pericarditis. In chronic pericarditis only small amounts may be present and a sample may not be obtainable.

** Necropsy Findings**

In acute cases there is gross distension of the pericardial sac with foul-smelling, grayish fluid containing flakes of fibrin, and the serous surface of the sac is covered by heavy deposits of newly formed fibrin. A cord-like, fibrous sinus tract usually connects the reticulum with the pericardium. Additional lesions of pleurisy and pneumonia are commonly present. In chronic cases the pericardial sac is grossly thickened and fused to the pericardium by strong fibrous adhesions surrounding loculi of varying size which contain pus or thin straw-colored fluid.

**Differential Diagnosis**

The typical clinical findings in pericarditis are chronic illness, toxemia, fever, congestive heart failure and muffled heart sounds. The major causes of congestive heart failure in cattle are pericarditis, endocardial disease, myocardopathy and cor pulmonale (pulmonary hypertension due to chronic pulmonary disease).

Pericarditis, lymphomatosis with cardiac involvement and congenital cardiac defects are all likely to be confused with traumatic pericarditis because of the similarity of the abnormal heart sounds.

- **Endocarditis** is usually associated with a suppurative process in another organ, particularly the uterus or udder, and although the abnormal heart sounds are typical bruits rather than pericardial friction sounds, this may be difficult to determine when extensive pericardial effusion has occurred.
- **Lymphomatosis** is usually accompanied by lesions in other organs or the presence of a marked leukocytosis and lymphocytosis.
- **Congenital cardiac defects** may not cause clinical abnormality until the first pregnancy but can be diagnosed by the presence of loud murmurs, a pronounced cardiac thrill and an absence of toxemia.
- Less common causes of abnormal heart sounds include thoracic tumors and abscesses, diaphragmatic hernia and chronic bloat, which cause distortion of the atria and atriocoronary orifices. They are associated with other diagnostic signs, particularly displacement of the heart.

- In severely debilitated animals or those suffering from severe anemia a hemic murmur which fluctuates with respiration may be audible.
- Occasional cases of hematogenous pericarditis are encountered, and in some cases of pasteurellosis a fibrinous pericarditis may be present, but there is usually serious involvement of other organs and the pericarditis is only secondary.

**Treatment**

The results of treatment are usually unsatisfactory but salvage of up to 50% of cases can be achieved by long-term treatment with antimicrobials. Rapid onset of generalized edema represents a poor prognosis. Drainage of the pericardial fluid may temporarily relieve the edema and respiratory embarrassment but relapse usually occurs within a few days. Selected cases of traumatic pericarditis have been treated satisfactorily by pericardiectomy.

**Prevention**

Prevention depends on preventing traumatic reticuloperitonitis through management of the environment and the administration of reticular magnets.

**Traumatic Splenitis and Hepatitis**

Traumatic splenitis and hepatitis occur relatively uncommonly as sequelae to traumatic reticuloperitonitis and are manifested either by continuation of the illness caused by the initial perforation or by apparent recovery followed by relapse several weeks later. The prominent clinical findings include fever (39.5–40.5°C, 103–105°F), tachycardia, gradual decrease in feed intake and milk yield but ruminal movements may be present and may be normal. Percussion of the abdomen over the site usually used to detect the pain of traumatic reticuloperitonitis gives a negative response although deep, forceful palpation may elicit a mild grunt. The diagnostic sign is pain on palpation with the thumb in the last two intercostal spaces halfway down the abdomen on the right side when there is hepatic involvement, and on the left side when the spleen is affected.

The total leukocyte count is elevated (above 12 000/μL) with a marked neutrophilia and a left shift. Rumenotomy is not usually undertaken except for diagnostic purposes. Treatment with antibacterial drugs is effective if commenced sufficiently early. Oral treatment with suflamidime has been effective in some cases.

**Impaction of the Omasum**

Omasal impaction as a clinical entity is difficult to define and is usually
Diseases of the abomasum

Diseases of the abomasum associated with metabolic disease, lactational stress and nutritional inadequacies are common in dairy cattle. The common diseases of the abomasum are:

- Left-side displacement of the abomasum (LDA)
- Right-side displacement of the abomasum (RDA)
- Abomasal torsion (volvulus)
- Abomasal ulcers
- Impaction associated with vagus indigestion
- Dietary abomasal impaction.

Their recognition is due in part to improved diagnostic techniques and increased awareness of their occurrence, but perhaps there is also an increase in their frequency because of intensified cattle production. Dairy cattle are being selected for high milk production and are being fed large quantities of grain and kept more commonly in total confinement where exercise is limited—all of which may contribute to abomasal atony, which is the precursor of abomasal displacements. A review of abomasal displacement in cattle is available.1

A number of general comments are summarized here that apply to most diseases of the abomasum.

CLINICAL EXAMINATION OF THE ABOMASUM

PHYSICAL EXAMINATION

The normal abomasum cannot usually be examined by the standard techniques of clinical examination except indirectly by auscultation and paracentesis. In LDA, the tympanitic sounds (pings) audible on auscultation and percussion between the middle to upper third of the ninth and 13th ribs and over the left paralumbar fossa are characteristic. In RDA, the tympanitic sounds (pings) audible on auscultation and percussion between the lower third of the ninth and 13th ribs and extending into the right paralumbar fossa, and the fluid-splashing sounds audible on auscultation and ballottement of the right lower to middle third of the abdomen, are characteristic. An enlarged abomasum may be palpable on rectal examination deep in the right lower quadrant of the abdomen depending on the size of the animal and the size of the distended abomasum, and provided the animal is not in advanced pregnancy.

In abomasal volvulus, the clinical findings are similar to right-side displacement but much more severe. On rectal palpation a fluid-filled abomasum feels tense; an impacted abomasum pits on digital pressure. (An impacted enlarged abomasum is usually situated slightly to the right of midline deep in the abdomen below the palpable kidney; it feels firm and does not pit on pressure.) In abomasal impaction, the enlarged, firm, doughy viscus can usually be palpated behind the lower aspect of the right costal arch but the gravid uterus of later pregnancy commonly makes this difficult. Following parturition the abomasum is more readily detectable by palpation through the abdominal wall or rectally.

ULTRASONOGRAPHY OF ABOMASUM

The abomasum can be visualized by ultrasonography over the ventral midline caudal to the xiphoid process and from both left and right paramedian regions lateral to the midline site. The abomasum can be clearly differentiated from adjacent viscera because of its contents, which appear as a heterogeneous, moderately echogenic structure with echogenic stippling.2 Abomasal motility cannot be observed but the relative size of the abomasum can be detected. Ultrasonographic examination of the abomasum of neonatal lambs provides an immediate indication of whether or not the lambs have sucked and may be useful in investigations of neonatal mortality.3

ABOMASOCENTESIS

Centesis of abomasal contents is a safe procedure if done carefully.5 Percutaneous ultrasound-guided abomasocentesis can be done to evaluate the nature and chemical composition of abomasal contents.6 The procedure is done at a site where the abomasum is large and no other viscerse are located. The optimum site for abomasocentesis is 10–27 cm caudal to the xiphoid process and on the ventral midline, or up to 10 cm caudal and to the right of it. A spinal needle (0.12 x 9.0 cm) with a stylet is guided by ultrasonography through the skin and abdominal wall and into the abomasum. Abomasal fluid is assessed for color, smell and the presence of blood, and pH. Normally, the color ranges from olive green to gray, and the fluid has a sour smell. The pH varies from 1.38–4.50. Higher values occur with abomasal hemorrhage, the presence of bile or chronic abomasitis due to ostertagiasis.

INTUBATION OF ABOMASUM

The abomasum of young calves can be intubated for experimental purposes.6

APPLIED ANATOMY AND PATHOPHYSIOLOGY OF THE ABOMASUM

In a healthy, nonpregnant cow, the abomasum is positioned below the rumen in the ventral part of the abdomen and is orientated towards the left side of the animal. During pregnancy, the enlarging uterus forces the abomasum into a more cranial position. This change is assumed to contribute to the development of an LDA, which generally occurs during the first 3 weeks after parturition.7

The anatomical position of the abomasum in cows during the last weeks of pregnancy and through the first 6 weeks after calving has been examined using ultrasonography.8,9 The uterus was always located on the ventral abdominal wall and the rumen had no contact with the ventral abdominal wall. During the last weeks of pregnancy, the abomasum was located in a small region of the left ventral side of the abdominal cavity. At parturition, the abomasum was positioned high on the left side and then descended. The abomasum was furthest from the midline immediately after calving. The position of the abomasum changed in a circadian rhythm. Eating and ruminating can influence its position. A pocket of the abomasum, the piform sac of the fundus, was detectable on the left side and was more pronounced when the abomasum was larger. Its position was related to the interval after calving, the feed intake and the pH and osmotic pressure of the rumen fluid.7 These findings explain, in
part, the high incidence of LDA in the first weeks after parturition. The pronounced lateral orientation of the abomasum predisposes the cow to development of left-side displacement.

The flow of rumen fluid into the abomasum can result in the production of carbon dioxide and methane gases, which when their absorption or the motility of the abomasum is decreased, are unable to escape from the blind pocket in the abomasum and may be a major factor in the pathogenesis of left side displacement. This may explain why 80% of displaced abomasums occur towards the left side.

The size of the blind pocket after calving may determine the development of a displacement on the left side. Cows with their abomasum in a high position would be expected to be at increased risk of a displacement. There is considerable variation between individual cows and having the abomasum in a high position was negatively associated with the animal’s feed intake after calving. Feed intake immediately after calving is negatively associated with body condition score during the dry period. High feed intakes were associated with a low position of the abomasum, which is probably a result of increased rumen filling: an enlarged rumen caused by a high feed intake forces the abomasum downwards. Thus inadequate feed intake is associated with displaced abomasum.

Diseases of the abomasum that cause stasis and accumulation of ingesta, fluid and gas in the viscus result in varying degrees of dehydration, metabolic alkalosis, hypochloremia and hypokalemia. The metabolic alkalosis and hypokalemia are often accompanied by muscular weakness and paradoxic aciduria. When these changes are severe, as in right-side dilatation, abomasal torsion and abomasal impaction, intensive fluid therapy is necessary for a favorable response. However, in spite of exhaustive efforts, because of irreversible abomasal atony the recovery rate is low.

Abomasal luminal pressure is increased in left-side displacement and in volvulus of the abomasum. This may be associated with the pathogenesis of ulceration in long-standing cases of LDA and with the prognosis of survival in abomasal volvulus. The luminal pressure is high in abomasal volvulus and higher in cattle that die or are sold for slaughter than in cattle that survive and are retained in the herd. Thus measurement of luminal pressure during surgery for volvulus may be of value in formulating prognosis for survival.

Abomasal hypomotility and a decreased rate of abomasal emptying are thought to be important factors in the etiology and pathogenesis of several diseases of the abomasum of adult cattle and calves. Because abomasal hypomotility has been associated with hypocalemia, endotoxemia, acidosis and alkalosis, hyperinsulinemia and hyperglycemia, the approach in treatment of suspected abomasal hypomotility in adult cattle and calves has been the correction of acid-base and electrolyte imbalances, control of the effects of endotoxemia and elimination of Gram-negative bacterial infections. Neostigmine, metoclopramide or erythromycin have been used in ruminants for the treatment of abomasal hypomotility on the basis that these drugs have a prokinetic effect in other animals. Prokinetic agents have the ability to stimulate, coordinate and restore gastric, pyloric and small-intestinal motility.

Erythromycin is an effective prokinetic agent in healthy sucking milk-fed calves similar to its effects in humans, dogs and horses. Intramuscular administration of erythromycin at 8.8 mg/kg increased the frequency of abomasal luminal pressure waves and the mean abomasal luminal pressure and decreased the half-time of abomasal emptying by 37%. Metoclopramide, neostigmine and low-dose (0.88 mg/kg) erythromycin did not alter abomasal motility, mean luminal pressure or emptying rate.

Abomasal emptying rate and volume in calves has been determined using nuclear scintigraphy and acetaminophen absorption methods. Ultrasonography has also been used to evaluate abomasal volume, location and emptying rate in sucking calves.

ABOMASAL REFUX

Reflux of abomasal fluid into the omasum and reticulorumen occurs when the abomasal fluid fails to move normally through the pylorus into the small intestine. This occurs most commonly in diseases of the abomasum, left-side displacement, right-side dilatation and vagus indigestion. Reflux may also occur in peritonitis, compression of the abomasum in advanced pregnancy, intussusception and toxemia. The rumen chloride levels increase from a normal of 10–25 mmol/L to 80–100 mmol/L and the buffering capacity of the rumen is decreased from 80–110 mmol/L to less than 50 mmol/L. Hypochloremic, hypokalemic metabolic alkalosis occurs. Treatment consists of removing excessive quantities of fluid from the rumen and the administration of large quantities of balanced electrolytes or simply saline intravenously. The intravenous administration of hypertonic saline solution, 1.8%, is effective for the correction of experimental hypochloremic metabolic alkalosis in sheep.

Duodenal–abomasal reflux occurs normally in cattle and may increase during abomasal displacement; the influx is lower in LDA than in RDA. The concentration of bile acids in the abomasum is twice as high in LDA and RDA as in healthy cattle.

A series of abomasal emptying defects in sheep were characterized by weight loss, anorexia, variable degrees of abdominal distension, increased concentrations of rumen chloride and grossly enlarged abomasum. No explanation for the emptying defect was found at necropsy.

The administration of apomorphine to sheep causes expulsion of acidic abomasal contents back into the preabomasal compartments without expulsion of gastric contents through the mouth — ‘internal vomiting’. In sheep, it is estimated that approximately 280 g of sodium bicarbonate given orally would be necessary to return the ruminal pH to the neutral range.

LEFT-SIDE DISPLACEMENT OF THE ABOMASUM

ETIOLOGY

The cause of LDA in cattle is multifactorial but is related primarily to feed intake before and after calving. The transition period occurring 2 weeks postpartum through 2–4 weeks postpartum is the major risk period in the etiology of LDA. The prepartum depression of feed intake and the slow postpartum increase in intake are risk factors causing decreased ruminal fill, reduced forage to concentrate ratio and increased incidence of other postpartum diseases. Excessive amounts of concentrate during the prepartum period increase the risk of left displaced abomasum, which may occur from the decreased ruminal fill caused by greater prepartum intake depression and reduced forage to concentrate ratio, decreased ruminal motility from lower ruminal fill and higher volatile fatty acid concentration, and decreased abomasal...
Etiology Gaseous distension and hypomotility of abomasum possibly due to feeding high levels of concentrate to dairy cattle in late pregnancy.

Epidemiology High-producing dairy cows within 6 weeks of calving. Insufficient crude fiber and roughage in ration. Concurrent disease such as hypocalcemia and ketosis may be risk factors but this is uncertain.

Signs Anappetence, ketosis, decreased milk production, abdomen usually smaller than normal, reticulorumen movements not clearly audible or absent, rumen pack not easily palpable, ping over left paralumbar fossa and cranial to it. Fatty liver and abomasal ulcers are possible complications.

Clinical pathology Ketonemia, ketonuria. Normal hemogram.

Lesions Not usually fatal.

Diagnostic confirmation Laparotomy to confirm displacement.

Differential diagnosis LDA must be differentiated from those common diseases of the forestomach and abomasum that cause anappetence to anoxia, ketosis, reduced or abnormal reticulorumen motility, and abnormal sounds on percussion and auscultation of the left abdomen. They are: simple indigestion, primary ketosis, traumatic reticuloperitonitis, vagus indigestion, fat cow syndrome.

Treatment Open and closed surgical techniques to replace abomasum and secure in normal position.

Control Avoid negative energy balance prepartum, avoid overconditioning of cows prepartum, provide optimal feed bunk management, maximize dry matter intake in late pregnancy.

Incidence Increased accumulation of abomasal gas. LDA is a disorder of throughput because of its relationship to diseases associated with high milk production and concentrate feeding. The practice of beginning to feed concentrates to high-producing dairy cattle during the last few weeks of the dry period in preparation for the transition to lactation after parturition (lead feeding) may be a high risk factor for LDA. Cows dried off in high body condition scores are at increased risk of LDA because of inadequate dry matter intake around the time of parturition.

High-level grain feeding increases the flow of ruminal ingesta to the abomasum, which causes an increase in the concentration of volatile fatty acids, which can inhibit the motility of the abomasum. This inhibits the flow of digesta from the abomasum to the duodenum so that ingesta accumulates in the abomasum. The large volume of methane and carbon dioxide found in the abomasum following grain feeding may become trapped there, causing its distension and displacement. However, the role of an increase in abomasal volatile fatty acid concentration as the cause of the abomasal atony is controversial.

Dietary crude fiber A crude fiber concentration of less than 16–17% in the diet of dairy cows was considered a significant risk factor for LDA. Some initial epidemiological studies indicated that cows affected with LDA were higher producers than their herdmates, and they were from higher-producing herds than herds without LDAs. The affected cows were also older and heavier than the average for cows examined in the survey.

Dietary protein A hospital-based case-control study of LDA: 17% compared to 1.6% in cows receiving loose alfalfa hay, sorghum silage and an 18% crude protein concentrate. The pelleted ration was finely ground and the short length of the dietary fiber may have been a risk factor by increasing volatile fatty acid and gas production.

In summary, feeding rations high in carbohydrates, inadequate levels of roughage and crude fiber levels below 17% during the last few weeks of pregnancy are probably important dietary risk factors.

Animal risk factors A hospital-based case-control study of LDA and abomasal volvulus in cattle based on the medical records of 17 North American veterinary teaching hospitals
over a period of 10 years compared risk factors for the two diseases.8

**Breed and age of cow**

LDA occurs predominantly in Holstein-Friesian cattle and a lower risk in Brown breed disposition for LDA has been investigated. Some studies have found higher risk of LDA occurring in Holstein-Friesian cattle and a lower risk in Brown Swiss cattle compared with the risk in Simmental–Red Holstein cross cows in Switzerland.9 In other studies, a breed disposition for displaced abomasum was found in Ayshire, Canadienne, Guernsey, Holstein–Friesian and Jersey cattle. In vitro studies of contractile activity of the abomasal wall of healthy cows of different breeds did not find any differences between breeds of cattle.9

The ratio of LDA to abomasal volvulus cases was 7.4 to 1. The risk for the two diseases increased with age with greatest risk at 4–7 years of age. Dairy cattle were at higher risk of developing LDA than beef cattle, with an odds ratio of 95. Female cattle were at a higher risk of developing LDA than male cattle, with an odds ratio of 29.

**Season of the year**

The odds of both diseases varied considerably throughout the year, with the lowest number of cases in the autumn. The odds of abomasal volvulus and LDA were highest in January and March, respectively. The greater incidence of the disease in the spring may also be related to the depletion of roughage supplies on farms in the Midwest region of the USA. In other regions of the world, the disease occurs throughout the year independently of the incidence of parturition.

**Influence of weather**

The possible effects of weather on the incidence of abomasal displacement has been examined.10 In a study over a period of 2 years, on 26 farms with a total of 6500 Holstein-Friesian lactating cows, 373 cases of abomasal displacement occurred. A change from sunny, warm and dry days to cool, overcast and humid days was associated with an increased incidence of displacement. There were no effect of either wind velocity or atmospheric pressure.

**Milk production**

The relationship between high milk yield or high milk yield potential and LDA has been examined in several studies and the results are inconclusive. In some observations, a higher incidence of the disease occurred in high-yielding cows. Later studies found no difference in herd milk yield between high- and low-incidence herds. Genetic correlations between LDA and production of milk and protein are very small and should be independent for selection. In some studies, dairy herds with a high mean PTA milk index were associated with a high occurrence of LDA.

**Late pregnancy**

Because parturition appears to be the most common precipitating factor, it has been postulated that during late pregnancy the rumen is lifted from the abdominal floor by the expanding uterus and the abomasum is pushed forward and to the left under the rumen. Following parturition, the rumen subsides, trapping the abomasum, especially if it is astatic or distended with feed, as it is likely to be if the cow is fed heavily on grain.

Proportionately fewer cases of abomasal volvulus than LDA occurred during the first 2 weeks after parturition – 28% and 57%, respectively.9 Because proportionately fewer cases of abomasal volvulus develop in the immediate postpartum period it is suggested that the rumen volume may directly influence the direction of abomasal displacement. On the basis of the findings, it is suggested that abomasal atony is a prerequisite for abomasal volvulus and LDA, and that existence of a less than full abdomen because of reduced rumen volume is a major risk and facilitates development of abomasal volvulus and LDA.9 It is suggested that normal rumen volume is an effective barrier against LDA and that high incidence of LDA in lactating dairy cattle is the result of the additive effects of decreased rumen volume, increased abdominal void immediately after parturition and increased exposure to factors that induce abomasal atony. Additional indirect evidence for the rumen barrier hypothesis is that feeding a high-roughage diet, containing at least 17% crude fiber, immediately prior to parturition is a commonly recommended and successful strategy for minimizing the incidence of LDA.

**Concurrent diseases**

Cows with an LDA are more likely to have had retained placenta, ketosis, stillborn calf, metritis, twins or parturient paresis than control cows.11,12 Concurrent diseases were present in 30% of abomasal volvulus cases and 54% of LDA cases. The greater incidence of concurrent disease in LDA suggests that inappetence and anorexia results in decreased rumen volume, which would predispose to displacement. Diseases of the wall of the abomasum (secondary ulcer) and ketosis and fatty liver are common concurrent diseases in dairy cows with LDA.8

**Pre-existing subclinical ketosis**

Ketosis is one of the most common complications of LDA but whether or not pre-existing subclinical ketosis is a risk factor for LDA has been controversial. Some clinical studies have reported that subclinical ketosis is a risk factor for LDA.4,13 The serum concentrations of aspartate transaminase (AST), the serum and milk beta-hydroxybutyrate and milk fat to protein ratio may be used in dairy cows during the first and second weeks after parturition as tests to predict the subsequent diagnosis of LDA.13,14 AST values between 100–180 U/L, and beta-hydroxybutyrate values between 1000–1600 μmol/L were associated with increased odds ratio and likelihood ratio of LDA. When cutoff values were increased, sensitivity decreased and specificity increased. The evaluation of two milk ketone tests as predictors of LDA in dairy cows within 2 weeks of parturition (median of 6 days postpartum and 12 days prior to the diagnosis of LDA) found high specificity but low sensitivity for prediction of subsequent occurrence of LDA.9 Increased ketone body concentration in milk is claimed to be a significant risk factor for LDA. This correlates with an increased fat to protein ratio in the first milk dairy herd improvement test as a predictor of subsequent LDA.15 However, the studies that conclude that pre-existing subclinical ketosis occurs before the occurrence of LDA, and is a risk factor (cause and effect relationship), do not provide evidence that the cause of the ketosis was not a pre-existing LDA. It is possible for the LDA to develop over a period of several days to a few weeks in susceptible cows, which would affect feed intake and contribute to the pathogenesis of ketosis. In addition, the sensitivity and specificity of the clinical diagnostic techniques (auscultation and percussion) are unknown and it is plausible that some cases of LDA are not recognized in their very early stages when the fundus of the abomasum has moved only a small distance up along the left lateral abdominal wall (see Anterior displacement under Clinical findings). The studies did not describe how the diagnosis of LDA was made. Cows with LDA are also twice as likely to have another disease than cows without LDA and the presence of those diseases could be risk factors for ketosis.

**Hypocalcemia**

Hypocalcemia, which occurs commonly in mature dairy cows at the time of parturition, has been suggested as an important contributing factor in LDA. Blood calcium levels affect abomasal motility; motility is normal down to a
threshold value of 1.2 mmol total calcium/L and below that level abomasal motility is absent. In a series of 510 dairy cows, those with hypocalcemia 12 hours before parturition (serum ionized calcium concentrations < 4.0 mg/dL or total serum calcium concentration < 7.9 mg/dL) had a 4.8 times greater risk of developing LDA than did normocalcemic cows. Other studies concluded that hypocalcemia is not an important risk factor for LDA. In cows with LDA, the ionized calcium is not significantly different from controls.

**Metabolic predictors of left side displacement of abomasum**

There is a predictive association of prepartum non-esterified fatty acids (NEFA) and postpartum beta-hydroxybutyrate concentrations with LDA. In cows with subsequent LDA, mean NEFA concentrations began to diverge from the means of cows without LDA 14 days before calving, whereas mean serum NEFA concentrations did not diverge until the day of calving. Prepartum, only NEFA concentration was associated with the risk of subsequent LDA. Between 0 and 6 days before calving, cows with NEFA concentration of 0.5 mEq/L or less were 3.6 times more likely to develop LDA after calving. Between 1 and 7 days postpartum, retained placenta, metritis and increasing serum concentration of beta-hydroxybutyrate and NEFA were associated with increased risk of subsequent LDA. Serum beta-hydroxybutyrate was a more sensitive and specific test than NEFA concentration. The odds of LDA were eight times greater in cows with serum beta-hydroxybutyrate levels of 1200 μmol/L or higher. Cows with milk beta-hydroxybutyrate concentration of 200 μmol/L or higher were 3.4 times more likely to develop LDA. Serum calcium concentration was not associated with LDA. In summary, the strategic use of metabolic tests to monitor transition dairy cows should focus on NEFA in the last week prepartum and beta-hydroxybutyrate in the first week postpartum.

**Genetic predisposition**

An inherited and breed predisposition to LDA has been suggested and examined but the results are inconclusive. The data of 7416 Canadian Holstein cows were examined to estimate genetic parameters for the most common diseases of dairy cows. The heritability of displaced abomasum across lactations was 0.28 and the estimates between displaced abomasum and production traits were small. In the hospital-based study in North America, the odds of LDA in Guernsey cattle were higher than in Holstein cattle.

**Miscellaneous animal risk factors**

Unusual activity, including jumping on other cows during estrus, is a common history in cases not associated with parturition. Occasional cases occur in calves and bulls but the disease occurs only rarely in beef cattle. Retained fetal membranes, metritis and mastitis occur commonly with LDA but a cause-and-effect relationship has been difficult to establish. In one retrospective study the disease was associated in terms of increased relative risk with periparturient factors such as stillbirth, twins, retained placenta, metritis, aciduria, ketonuria and low milk yield in the previous lactation.

**Economic importance and effects on production and survival**

The economic losses from the disease include lost milk production during the illness and postoperatively, and the cost of the surgery. The effects of LDA on test-day milk yields from 12,572 cows from parities 1–6 over a 2-year period were evaluated. From calving to 60 days after diagnosis, cows with LDA yielded on average 557 kg less milk than cows without LDA and 30% of the losses occurred before diagnosis. Milk loss increased with parity and productivity and milk losses were greatest in highest-yielding cows. Cows with LDA were nearly twice as likely to have another disease as were cows without LDA. Cows with LDA are more likely to be removed from the herd at any point in time after the diagnosis than their herdmates. Cows with LDA survived a median of 12 months, and control cows survived a median of 27 months. Low milk production is a common reason for removal of cows with an LDA and the probability of removal increased as lactation number increased.

**PATHOGENESIS**

In the nonpregnant cow, the abomasum occupies the ventral portion of the abdomen very nearly on the midline, with the pylorus extending to the right side cephalic to the omasum. As pregnancy progresses, the enlarging uterus occupies an increasing amount of the abdominal cavity. The uterus begins to slide under the caudal aspects of the rumen, reducing rumen volume by one-third at the end of gestation. This also forces the abomasum forward and slightly to the left side of the abdomen, although the pylorus continues to extend across the abdomen to the right side. After calving, the uterus retracts caudally towards the pelvic inlet, which under normal conditions allows the abomasum to return to its normal position.

During LDA, the pyloric end of the abomasum slides completely under the rumen to the left side of the abdomen.

The relative lack of rumen fill and abomasal atony allows the abomasum to distend and move into the left side of the abdomen.

A decline in plasma concentration of calcium around the time of parturition may contribute to the abomasal atony.

Normally, the abomasum contains fluid and is located in the ventral part of the abdomen. In postpartum cows, the abomasum may shift to the left without causing any clinical signs. Abomasal atony and gaseous distension are considered to be the primary dysfunctions in LDA. The existence of abomasal atony precedes distension and displacement of the abomasum. The gas accumulated in the abomasum consists mainly of methane (70%) and carbon dioxide. In a normal abomasum, the gas production is equal to the clearance in an oral or aboral direction. When motility of the abomasum is inadequate, accumulation of gas occurs. The origin of the excess gas is uncertain but there is evidence that the gas in the abomasum originates from the rumen in association with increased concentrate feeding and an increase in volatile fatty acid concentrations in the abomasum. A high-grain, low-forage diet can promote the appearance of volatile fatty acids in the abomasum by reducing the depth of the ruminal mat or raft (consisting primarily of the long fibers of forages). Physical reduction of forage particle length by chopping forages too finely prior to ensiling or overzealous use of mixer wagons also can contribute to loss of rumen fill. The rumen raft captures grain particles so that they are fermented at the top of the ruminal fluid. The volatile fatty acids produced at the top of the ruminal fluid are generally absorbed from the rumen with little volatile fatty acid entering the abomasum. In cows with an inadequate rumen raft, grain particles fall to the ventral portion of the rumen and reticulum, where they are fermented or pass on to the abomasum. The volatile fatty acids produced in the ventral rumen can pass through the rumenoreticular orifice to enter the abomasum before the rumen can absorb them. A thick ruminal raft is generally present during the dry period, when cows are fed a high forage diet, but the depth of the raft is rapidly reduced in early lactation, especially if dry matter intake decreases. Also, when cows are fed a higher grain ration, there is less regurgitation of the cud and mastication, and less saliva produced, which affects buffering of the rumen.

The amount of effective fiber determines the consistency and depth of the rumen raft and stimulates rumen contractions.

Total mixed rations that are easily sorted by cows may affect the ratio of
forage to concentrate of total feed consumed, which contributes to the development of an LDA.

The atonic gas-filled abomasum becomes displaced under the rumen and upward along the left abdominal wall, usually lateral to the spleen and the dorsal sac of the rumen. It is primarily the fundus and greater curvature of the abomasum that becomes displaced, which in turn causes displacement of the pylorus and duodenum. Based on epidemiological observations presented earlier, it is hypothesized that a reduced rumen volume in the immediate postpartum period when there is some abdominal void allows this displacement to occur. The omasum, reticulum and liver are also displaced to varying degrees. The displacement of the abomasum invariably results in rupture of the attachment of the greater omentum to the abomasum. In some cases, the LDA resolves spontaneously, such cases are known as 'floaters'.

Insulin resistance is common in cows with an LDA. High insulin concentrations associated with hyperglycemia but independent of ketosis are common in cows with LDA. In-vitro studies of abomasal motility indicate that the contractions of the longitudinal muscle from the pyloric myenteric plexus of cows with an LDA or RDA are significantly reduced compared to muscle from normal cows. In cows with an LDA and high concentrations of blood glucose and insulin, the myoelectrical activity of the abomasum was reduced, but increased following surgical correction along with a decrease in the concentrations of glucose and insulin.

Compression by the rumen of the impounded part of the abomasum causes a great decrease in the volume of the organ and interference with normal movements. There is probably some interference with the function of the esophageal groove due to slight rotation of all the stomachs in a clockwise direction, and this impedes forward passage of digesta. The obstruction of the displaced segment is incomplete and, although it contains some gas and fluid, a certain amount is still able to escape and the distension rarely becomes severe. There is no interference with blood supply to the trapped portion so that effects of the displacement are entirely those of interference with digestion and movement of the ingesta, leading to a state of chronic inanition. In occasional cases the abomasum becomes trapped anteriorly between the reticulum and diaphragm – anterior displacement of the abomasum.

A mild metabolic alkalosis with hyperchloremia and hypokalemia are common, probably because of the abomasal atony, continued secretion of hydrochloric acid into the abomasum and impairment of flow into the duodenum. Affected cattle usually develop secondary ketosis which, in fat cows may be complicated by the development of the fatty liver syndrome. Endotoxemia does not occur in LDA or RDA.

Abomasal luminal gas pressure, volume and perfusion in cows with LDA or abomasal volvulus

The luminal pressure in LDA is increased (median 8.7 mmHg; range 3.5–20.7 mmHg), which may contribute to the pathogenesis of abomasal ulceration. Abomasal luminal pressure and volume is higher in cattle with an abomasal volvulus than in cattle with an LDA. Abomasal perfusion decreases as luminal pressure increases in cattle with an abomasal volvulus or LDA.

Perforating abomasal ulceration

Perforating abomasal ulceration and acute local peritonitis with fibrinous adhesions also occur in some cases of LDA. Abdominal pain and pneumoperitoneum are common sequelae. The ulcers may perforate acutely and cause rapid death due to acute diffuse peritonitis. Duodenal ulceration has also been associated with LDA.

CLINICAL FINDINGS

General appearance and ketosis

Usually within a few days or a week following parturition there will be inappetence, sometimes almost complete anorexia, a marked drop in milk production and varying degrees of ketosis, based on ketonuria and other clinical findings of ketosis. It is not uncommon to diagnose an LDA that was treated for ketosis, improved for a few days and then relapsed.

On inspection of the abdomen, the left lateral abdomen appears 'slab-sided' because the rumen is smaller than normal and displaced medially. The temperature, heart rate and respirations are usually within normal ranges. The feces are usually reduced in volume and softer than normal but periods of profuse diarrhea may occur.

Status of reticulorumen and spontaneous abomasal sounds

Ruminal movements are commonly present but decreased in frequency and intensity, and sometimes inaudible even though there are movements of the left paralumbar fossa indicating rumen motility. In some cases, the rumen pack is palpable in the left paralumbar fossa, and the rumen contractions and sounds can be detected in the fossa as in normal cows. However, the rumen sounds may not be audible over an area anterior to the fossa where they are also audible in normal cows. The absence of normal ruminal sounds in the presence of abdominal ripples suggests the presence of an LDA.

Auscultation of an area below an imaginary line from the center of the left paralumbar fossa to just behind the left elbow reveals the presence of high-pitched tinkling sounds, which often have a progressive peristaltic character. These are abomasal sounds and may occur several times per minute or infrequently (as long as 5 min apart). They are not related in occurrence to ruminal movements and this can be ascertained by simultaneous auscultation over an area between the upper third of the ninth and 12th ribs and palpation of the left paralumbar fossa for movements of the dorsal sac of the rumen. While auscultating over the same area and ballotting the left lower abdomen just below the fossa, high-pitched fluid-splashing sounds of the LDA are commonly audible.

Pings of the left-side displacement of the abomasum

Percussion, using a flick of the finger or a plexor, and simultaneous auscultation over an area between the upper third of the ninth and 12th ribs of the abdominal wall commonly elicits the high-pitched tympanic sounds (pings) that are characteristic of LDA. These pings may not be present if the cow has just previously been transported to a clinic for surgery but they will commonly reappear in 24–48 hours. Occasionally, careful, repeated, time-consuming examinations using percussion and simultaneous auscultation are necessary to elicit the pings.

Acute left-side displacement of the abomasum

In rare cases there is initially a sudden onset of anorexia accompanied by signs of moderate abdominal pain and abdominal distension. These are the acute cases, which are uncommon. An obvious bulge caused by the distended abomasum may develop in the anterior part of the upper left paralumbar fossa and this may extend up behind the costal arch almost to the top of the fossa. The swelling is tympanic and gives a resonant note on percussion. In acute cases the temperature may rise to 39.5°C (103°F) and the heart rate to 100/min but in the more common subacute cases the temperature and pulse rate are normal. The appetite returns but is intermittent and selective, the animal eating only certain feeds, particularly hay. There may be transitory periods of improvement in appetite and disappearance of these sounds, especially after transport or vigorous exercise.
**Concurrent perforating abomasal ulceration**

Perforating abomasal ulceration occurs concurrently in some cases of LDA, resulting in localized peritonitis and pneumoperitoneum.24 Affected cattle have the pin going over the left abdomen typical of an LDA, but a pin going over both the right and left paralumbar fossae due to pneumoperitoneum is also common. Abdominal pain due to the local peritonitis is characterized by tensing of the abdominal wall, grunting and arching of the back on deep palpation over the abomasal area. The peritonitis is associated with a fever. The prognosis in these cases is unfavorable.

**Other clinical features**

**Ultrasound examination**

Ultrasound examination can assist in the diagnosis of abomasal displacements.25 In cattle with LDA the abomasum is seen between the left abdominal wall and the rumen. It contains fluid ingesta ventrally and a gas cap of varying size dorsally. Occasionally, the abomasal folds are seen in the ingesta. In cattle with RDA, the liver is displaced medially from the right abdominal wall by the abomasum, which has an ultrasonographic appearance similar to that described for left displacement.

**Rectal examination**

On rectal examination a sense of emptiness in the upper right abdomen may be appreciated. The rumen is usually smaller than expected and only rarely is the distended abomasal palpable to the left of the rumen. Occasionally, there is chronic ruminal tympany.

Secondary ketosis and fatty liver

Cows in fat body condition at parturition commonly have severe ketosis and the fatty liver syndrome secondary to LDA. The disease is not usually fatal but affected animals are usually less than satisfactory production units.

**Left-sided displacement of abomasum**

In anterior displacement, the distended abomasum moves in a cranial direction and becomes trapped between the reticulum and the diaphragm. In one series of 161 cases of abomasal displacement, anterior displacement accounted for 12% of all cases.26 The clinical findings are similar to those described above except that the characteristic LDA pings cannot be elicited over the typical region. Normal rumen contractions can be heard in the usual position and gurgling sounds characteristic of a distended abomasum may be audible just behind and above the heart and on both sides of the thorax.26 It is necessary to auscultate over the ventral left abdominal wall, especially over an area extending from the middle of the sixth to eighth ribs, above and below an imaginary line drawn between the point of the elbow and the tuber coxae. If a rumenotomy is done the distended abomasum can be felt between the reticulum and diaphragm.

**Atrial fibrillation**

A paroxysmal atrial fibrillation is present in some cases, which is considered to be caused by a concurrent metabolic alkalosis. Following surgical correction the arrhythmia usually disappears.

Course of left-side displacement of the abomasum

The course of an LDA is highly variable. Undiagnosed cases usually reach a certain level of inanition and may remain at an equilibrium for several weeks or even a few months. Milk production decreases to a small volume and the animal becomes thin, with the abdomen greatly reduced in size.

Unusual cases of left-side displacement

Occasional cases occur in cows that are clinically normal in all other respects. In one case, a cow had an LDA, which was confirmed at necropsy, for 1.5 years, during which time she calved twice and ate and produced milk normally.

Left-side displacement of the abomasum in calves

In calves, the clinical findings include inappetence, reduced weight gain, recurrent distension of the left paralumbar fossa and a metabolic ping and fluid-splashing sounds on auscultation and percussion of the left flank.

**CLINICAL PATHOLOGY**

**Hemogram**

There are no marked changes in the hemogram unless there is intercurrent disease, particularly traumatic reticuloperitonitis or abomasal ulcer. A moderate to severe ketonuria is always present but the blood glucose level is within the normal range. There is usually a mild hemococoncentration evidenced by elevations of the packed cell volume (PCV), hemoglobin and total serum protein. A mild metabolic alkalosis with slight hypochloremia and hypokalemia may also be present.

**Serum biochemistry**

Ketosis is the most common complication of LDA and severe cases of ketosis are commonly accompanied by fatty liver. The blood levels of AST and beta-hydroxybutyrate can be measured in dairy cows during the first and second weeks after parturition as possible tests to predict the subsequent diagnosis of LDA.14 AST values between 100-180 U/L and beta-hydroxybutyrate values between 1000-1600 μmol/L were associated with increased odds ratio and likelihood ratio of LDA.

In cows with fatty liver, plasmalipoprotein concentrations are decreased. In addition to those of lipoprotein lipids, concentrations of apolipoprotein B-100 (apo-B-100), the major apoprotein in very low-density lipoproteins and low-density lipoproteins, and apolipoprotein A-1 (apo-A-1), the predominant protein constituent of high-density lipoprotein, also are reduced in cows with fatty liver. Decreased serum levels of apo-B-100 and apo-A-1 occur in cows with ketosis and LDA and may be used during the stages of nonlactation and early lactation to predict cows susceptible to ketosis and LDA.27 Dairy cows with LDA also have low plasma and liver α-tocopherol, and plasma vitamin E values may decrease in cows with increased liver triglyceride content.28

A mild hypocalcemia is usually present but parturient hypocalcemia is uncommon.

**Cowside tests of milk and urinary ketones**

Milk ketone tests can also be used as predictors of LDA in dairy cows within 2 weeks of parturition.4 In the first week of lactation, the Pink test liquid and the Ketolac test strip were highly sensitive for the detection of subclinical ketosis when used in milk.29 The Ketotest (a milk beta-hydroxybutyrate test strip) is also highly sensitive for the detection of subclinical ketosis.30

Urine ketones: the Ketostix (urine nitroprusside strip detecting acetocacetate) can be used on a regular basis to detect subclinical ketosis.30

**Metabolic predictors of left side displacement of abomasum**

Metabolic tests to predict the occurrence of LDA can be used strategically in the last week prepartum and the first week postpartum12 (details under Metabolic predictors of left side displacement of abomasum, in Animal risk factors, under Epidemiology, above).

**Liver function**

Cows with LDA may have varying degrees of fatty liver.31-33 In liver biopsy samples, more about 55% of cows with LDA, fatty degeneration may be present.31 In some cows with LDA, liver biopsies found 31% fat infiltration and in those same animals, serum AST and gamma-glutamyl transferase levels were increased.32

**Abomasocentesis**

Centesis of the displaced abomasum through the 10th or 11th intercostal space in the middle of the third abdominal wall may reveal the presence of fluid with no protozoa and a pH of 2. Ruminal fluid will
have protozoa and a pH of between 6 and 7. Fluid is not always present in appreciable quantity in the abomasum and a negative result on puncture cannot be interpreted as eliminating the possibility of abomasal displacement.

**Necropsy Findings**

The disease is not usually fatal but carcasses of affected animals are sometimes observed at abattoirs. The displaced abomasum is trapped between the rumen and the ventral abdominal floor and contains variable amounts of fluid and gas. In occasional cases it is fixed in position by adhesions, which usually arise from an abomasal ulcer. Fatty liver is common in cows that died from complications of LDA within a few days of parturition or following surgery.

**Differential Diagnosis**

Left-side displacement of the abomasum occurs most commonly in cows within a few days of parturition and is characterized by gauze, a relatively slab-sided left abdomen and secondary ketosis. The characteristic pings can usually be elicited by percussion and auscultation. The presence of secondary ketosis in a cow immediately after parturition should arouse suspicion of the disease. Primary ketosis usually occurs in high-producing cows 2–6 weeks after parturition. The response to treatment of primary ketosis is usually permanent when treated early, while the response to treatment of the ketosis due to LDA is temporary and a relapse in a few days is common.

Left-side displacement of the abomasum must be differentiated from those common diseases of the forestomach and abomasum that cause inappetence to anorexia, ketosis, reduced or abnormal reticulorumen motility, and abnormal sounds on percussion and auscultation of the left abdomen.

**Common differentials**

- **Simple indigestion** is characterized by normal vital signs, inappetence to anorexia, history of change of feed, reduced milk production, a relatively full rumen with reduced frequency and intensity of contractions, the absence of pings and spontaneous recovery in 24 hours.
- **Primary ketosis** is characterized by inappetence, decline in milk production, strong ketonuria, normal vital signs, full rumen with reduced frequency and intensity of contractions, dry but normal amount of feces and response to therapy with dextrose and propylene glycol in 12–24 hours.
- **Traumatic reticuloperitonitis** in its acute form is characterized by ruminal stasis, mild fever, a grunt on deep palpation over the xiphoid sternum and a slight neutrophilia with a regenerative left shift. However, in subacute and chronic traumatic reticuloperitonitis a painful grunt may be absent, the temperature and hemogram may be normal and on auscultation and percussion the reticulum may be mistaken for an LDA. The tympanic sounds of an atonic rumen occur over a larger area than with LDA and are not as high-pitched as those of LDA – they have been called ‘pungs’. An exploratory laparotomy may be necessary to distinguish between the two, although laparoscopy, ultrasonography and abdominocentesis are alternatives.

**Vagus indigestion** is characterized by progressive abdominal distension due to a grossly distended rumen with or without an enlarged abomasum, and is more common before parturition. Dehydration is also common.

**Fatty cow syndrome** at parturition is characterized by excessive body condition, inappetence to anorexia, ketonuria, reduced or absent reticulorumen motility, and usually no pings over the rumen.

**Treatment**

Surgical correction is now commonly practiced and several techniques have been devised with emphasis on avoidance of recurrence of the displacement.

**Open surgical techniques**

**Right paramedian abomasopexy** and **right paralumbar fossa omentopexy** are the most widely used means of correcting left displacement of the abomasum. The right paralumbar fossa omentopexy is popular because the animal is standing and the surgeon can work alone without assistance. More skill is required than for the right paramedian abomasopexy. The right paramedian abomasopexy requires less manipulation because the abomasum usually returns to its normal position when the cow is placed in dorsal recumbency. The major disadvantage is the number of people required to restrain the animal in dorsal recumbency. There is little difference in the cost of doing a right paramedian abomasopexy compared to a right paralumbar fossa omentopexy, of which there are modifications from the original description. Based on field studies there is also no difference in either the reproductive performance or incisional complications following surgery. Based on milk yield at 1 month after surgery, some results indicate a slight preference for a right paramedian abomasopexy.

**Closed suture techniques**

A few closed suturing abomasopexy techniques have been advocated because they are rapid and inexpensive but the complications that can occur indicate that laparotomy and omentopexy are desirable. In the blind suture technique, the precise location of insertion of the sutures is unknown. Complications include peritonitis, cellulitis, abomasal displacement or evisceration, complete forestomach obstruction and thrombophlebitis of the subcutaneous abdominal vein.

**Roll-and-toggle-pin suture procedure**

The roll-and-toggle-pin suture, a modification of the closed suture technique, is also available and has been compared with right paralumbar fossa pyloro-omentopexy. The roll-and-toggle technique, as with other closed repositioning and stabilization techniques, is generally less expensive and provides results comparable with the open surgical techniques.

Advantages of the closed suture technique include confirmation of suture placement in the abomasum by identification of abomasal gas, and deflation of the abomasum during correction.

Cows with LDA corrected by toggle-pin suture procedure produced less milk than control cows, and all the decrease in production occurred in the first 4 months of lactation.

The occurrence of LDA did not affect the period from calving to conception, nor did it affect subsequent conception rate, but it was associated with an extended period between calving and first postpartum artificial insemination.

A higher proportion of LDA cattle were sold or died. Death and culling were more pronounced immediately after the diagnosis of LDA and the toggle-pin suture procedure.

**Survivorship following surgery to correct left-side displacement of the abomasum**

In a series of 564 cases of displaced abomasum (466 LDA, 98 RDA), survival after surgery was evaluated after 10 days and 15 months. More LDA than RDA cows were discharged as cured (82% vs 74%). However, survival after the early postsurgical period was similar for RDA and LDA cows. In LDA cows, the factors associated with a favorable prognosis were a short duration of disease, an undisturbed general condition, good appetite, normal feces, a higher body weight, lower hematocrit, hemoglobin and erythrocyte counts, lower urea, AST and bilirubin, and higher serum sodium, potassium and chloride concentrations compared with cows with an unfavorable prognosis. A thorough clinical and laboratory examination with special emphasis on general physical condition, liver function and dehydration status are important in determining the prognosis of abdominal surgery in LDA.
Treatment of ketosis
Parenteral dextrose and oral propylene glycol are necessary for treatment of the ketosis and to avoid fatty liver as a complication. Postsurgical convalescence of cows with LDA is clearly related to disturbances in energy metabolism and fatty liver. During convalescence, in cows with no fatty liver or moderate fatty liver, the feed intake and daily milk production increases steadily. In cows with severe fatty liver feed intake remains low. This emphasizes the need for effective treatment of excessive lipomobilization, ketosis and fatty liver along with surgical correction of the LDA. All cases of LDA should be corrected as soon as possible to minimize the incidence of peritoneal adhesions and abomasal ulcers, which may perforate and cause sudden death.

Rumen transfaunation following surgery for left-side displacement of the abomasum
The administration of 10 L of rumen fluid via a stomach tube immediately after surgical correction of an LDA, and on the next day, resulted in a beneficial effect characterized by a greater feed intake, less degree of ketonuria and higher milk yield compared to control cows given water.

CONTROL
The transition period occurring 2–3 weeks before and after calving is a major risk period in the etiology of LDA. The prepartum depression of dry matter intake and the slow postpartum increase in dry matter intake are risk factors causing lower ruminal fill, reduced forage to concentrate ratios (in nontotal mixed ration feeding systems) and increased incidence of other postpartum diseases. Retained fetal membranes, metritis and either clinical or subclinical ketosis and hypocalcemia are probable risk factors for LDA. Excessive amounts of concentrate, or too rapid an increase in concentrate feeding during the peripartum period, increases the risk of LDA, as higher volatile fatty acid concentration in the abomasal contents leads to decreased abomasal motility and emptying and excess gas in the abomasum. (See further details of importance of crude fiber intake in the rumen and its effect on the abomasum under Pathogenesis, above.)

Prepartum nutrition and management
Reduction of the incidence of LDA in a dairy herd can be achieved by optimal nutrition and management during the dry period. The following principles are important:
- Avoid a negative energy balance prepartum by avoiding overconditioning and by providing optimal feed bunk management to cows in late gestation
- Feed some concentrates prior to calving to insure development of ruminal papillae
- Maximize dry matter intake in the immediate postpartum period
- Ensure palatable feed and water available to periparturient cows at all times
- Feed bunk management must ensure that cows have adequate access to fresh feed at all times to maximize dry matter intake in late pregnancy and thus improve energy balance
- Energy density of prepartum diets should not exceed 1.65 Mcal of NE/kg of DM.

Every effort should be made to minimize dietary alterations near parturition that could result in indigestion. The amount of grain and corn (maize) silage fed prepartum should be kept at a minimum, while other forages are fed ad libitum.

Several experiments have shown no response in production to feeding large quantities of grain or concentrates (lead feeding) before parturition when cows were in good condition at drying-off and were fed well following parturition. Consequently, there seems little reason to continue the practice of steaming-up cows before parturition.

Crude fiber intake
Ensuring an adequate intake of a high-fiber diet to dairy cows during the ‘far-off’ and ‘close-up’ periods in late pregnancy and the immediate ‘postfreshening’ period is of critical importance to the prevention of this disease. The high-fiber diet will physically expand the rumen and provide a barrier against abomasal migration. The basic principle is to maintain adequate ruminal filling before and after calving. This requires careful analysis and implementation of the dry cow feeding program. Readers are referred to National Research Council, 2001 (see Review literature) for details on feeding programs for dairy cattle.

The emphasis in the dry cow feeding program must be on increasing dry matter intake, increasing particle length and effective fiber content of the ration. Feeding a high-roughage diet is consistent with one of the most commonly recommended and successful management strategies for minimizing LDA during the postpartum period. This means insuring adequate fiber content of at least 17%. An adequate level of fiber will also aid in the control of subacute ruminal acidosis, which may occur when dairy cows are fed grain in the latter part of the dry period in preparation for lactation.

Monensin in controlled-release capsule prepartum
Monensin is an ionophore antibiotic that alters volatile fatty acid production in the rumen in favor of propionate, which is a major precursor for glucose in the ruminant. A monensin controlled-release capsule is available as an aid in the prevention of subclinical ketosis in lactating dairy cattle. The device delivers 335 mg of monensin per day for 95 days. A monensin controlled-release capsule has been shown to decrease the incidence of subclinical ketosis, displaced abomasum and multiple illnesses when administered to dairy cows 3 weeks before calving. It is likely that these effects on clinical health are mediated by improved energy balance in monensin-supplemented cows. There are improvements in energy indicators such as increased glucose and decreased beta-hydroxybutyrate after calving.

The administration of a monensin controlled-release capsule to cows 3 weeks prepartum significantly decreased NEFA and beta-hydroxybutyrate and significantly increased concentrations of serum cholesterol and urea in the week immediately precalving. No effect of treatment was observed for calcium, phosphorus or glucose in the precalving period. After calving, concentrations of phosphorus were lower and beta-hydroxybutyrate tended to be lower, and cholesterol and urea were higher in monensin-treated cows. There was no effect of treatment on NEFA, glucose or calcium in the first week after calving. Monensin treatment administered precalving significantly improved indicators of energy balance in both the immediate precalving and postcalving periods. The prevalence of subclinical ketosis as measured by cowside tests was lower in monensin-treated cows. These findings indicate more effective energy metabolism in monensin-treated cows as they approach calving, which is important for the prevention of retained placenta, clinical ketosis and displaced abomasum. In general, a 40% reduction in both LDA and clinical ketosis can be expected with precalving administration of monensin controlled-release capsules. In addition, a 25% decrease in retained placenta may occur.

Genetic selection
There is some evidence that LDA is a moderately heritable trait and that the incidence may be lowered by genetic selection. However, this has not been explored on a practical basis.
**RIGHT-SIDE DISPLACEMENT OF THE ABOMASUM AND ABOMASAL VOLVULUS**

### Etiology

Abomasal atony associated with high-level grain feeding. Cause in calves unknown

### Epidemiology

**Occurrence and incidence**

Lactating dairy cows

Dilatation, RDA and abomasal volvulus occurs primarily in adult dairy cows, usually within the period 3–6 weeks after calving. The disease is being recognized with increased frequency because of improvements in diagnostic techniques and perhaps because more cows are being fed intensively for milk production. Incidence data based on individual dairy herds are not available but based on cases of abomasal disease admitted to a veterinary teaching hospital the ratio of abomasal volvulus to LDA was 1 to 7.4.

Beef cattle

Abomasal displacement and volvulus has been described in beef cattle breeds from 1 month to 6 years of age with a median age of 10 months. The typical case was under 1 year of age.

### Risk factors

There is little information available on the epidemiology of right-side displacement of the abomasum and abomasal volvulus. Most of the risk factors described for LDA are relevant to RDA and abomasal volvulus. The feeding of high levels of grain to high-producing dairy cows in early lactation is considered to be a major risk factor. However, there are no reliable data to support this cause-and-effect relationship. Why the disease occurs in a small percentage of high-producing dairy cattle being fed high-level grain rations is unknown.

When this disease was originally described, the incidence appeared to be higher in Scandinavian countries than elsewhere. The risk factors in those situations were not identified but it was thought that indoor winter feeding and the shift of the acid–base balance to an alkalotic state during the winter months might be important factors. In Denmark, the ingestion of large quantities of soil particles on unwashed root crops used as feed is considered to be significant. This may be the reason for the higher incidence of the disease in the later part of the winter. However, attempts to reproduce the condition by feeding large quantities of soil particles have not been successful.
quantities of sand have been unsuccessful. Because atony is often associated with vagus indigestion, a relationship between the two has been suspected but there are usually no lesions affecting the reticulum or vagus nerves.

A hospital-based epidemiological study of the risk factors for abomasal volvulus and FDA was performed using the medical record abstracts derived from the veterinary teaching hospitals of 17 North American veterinary schools. The risk for abomasal volvulus increased with increasing age, with a greater risk in dairy cows 4–7 years of age. Dairy cattle were at a much higher risk than beef cattle. Approximately 28% of cases of abomasal volvulus occurred within the first 2 weeks and 52% within 1 month following parturition. This indicates that proportionately fewer cases of abomasal volvulus than left displacement occur during the first 2 weeks following parturition. The hospital case fatality rate for abomasal volvulus and LDA was 23.5%, and 5.6%, respectively.

It is suggested that abomasal atony is a prerequisite for the development of right-side displacement and abomasal volvulus, and that following parturition the abdominal void facilitates such development. The direction of the displacement could be influenced predominantly by the volume of the forestomach. Immediately after parturition, displacement occurs to the left because of a reduction in the size of the rumen volume. Several weeks later the dilated abomasum moves caudally and dorsally in the right abdomen because the volume of the forestomach is much larger thereby providing an effective barrier (rumen barrier).

Abomasal volvulus has also occurred following correction of LDA by casting and rolling.

PATHOGENESIS

Dilatation and displacement phase

In RDA, abomasal atony occurs initially, resulting in the accumulation of fluid and gas in the viscus leading to gradual distension and displacement in a caudal direction on the right side (dilatation phase). During the dilatation phase, which commonly extends over several days, there is continuous secretion of hydrochloric acid, sodium chloride and potassium into the abomasum, which becomes gradually distended and does not evacuate its contents into the duodenum. This leads to dehydration and metabolic alkalosis with hypochloremia and hypokalemia. These changes are typical of a functional obstruction of the upper part of the intestinal tract and occur in experimental RDA and experimental obstruction of the duodenum in calves.

The abomasal luminal pressure in naturally occurring abomasal volvulus is increased (median 11.7 mmHg; range 4.1–32.4 mmHg). Increased luminal pressure in abomasal volvulus could cause mucosal injury by local vascular occlusion and affect the prognosis. Among cattle with abomasal volvulus, the abomasal luminal pressure was significantly higher in those that died or were sold following surgery (median 20.6 mmHg) than in cattle that recovered and were retained in the herd (median 11.0 mmHg). Calculation of likelihood ratios suggest that selecting cattle with a value of 16 mmHg for luminal pressure optimized the distribution of cattle into productive and nonproductive groups.

The abomasal luminal gas pressure and volume were higher in cattle with an abomasal volvulus than in cattle with an LDA. As luminal gas pressure increases, abomasal perfusion decreases, resulting in varying degrees of ischemia to the abomasal mucosa. In cows with an abomasal volvulus, lactate concentration in the gastroepiploic vein was greater than that in the jugular vein, whereas no difference in lactate concentrations was detected in cows with an LDA. This indicates that cattle with a large and densely distended abomasum associated with a volvulus or LDA should have the vescus decompressed as soon as possible to minimize the potential for ischemia-induced injury to the abomasal mucosa, which may result in ulcers and perforations.

An experimental model of hypochloremic metabolic alkalosis by diversion of abomasal outflow in sheep has been described. A similar model in adult lactating dairy cows resulted in weakness and depression in 10–12 hours, dehydration, hypochloremia, hypokalemia, hypocalcemia and a milk alkalosis. Up to 35 L of fluid may accumulate in the dilated abomasum of a mature 450 kg cow, resulting in dehydration, which will vary from 5–12% of body weight. In uncomplicated cases, there is only slight hemococoncentration and a mild electrolyte and acid–base imbalance, with moderate distension of the abomasum. These cases are reversible with fluid therapy. In complicated cases there is severe hemococoncentration, hypovolemia and dehydration and marked metabolic alkalosis with a severely distended abomasum. The degree of dehydration is a reliable preoperative prognostic aid. The hypovolemia, compression of the caudal vena cava and stimulation of the sympathetic nervous system in response to distension and twisting of the abomasum results in tachycardia, which is also a reliable preoperative prognostic aid.

In cattle with severe and prolonged abomasal volvulus, a metabolic acidosis may develop and be superimposed on the metabolic alkalosis, leading to a low base excess concentration of extracellular fluid. In the experimental disease in sheep, the metabolic acidosis observed terminated, was associated with an increase in plasma lactate concentration probably due to hypovolemic shock and anaerobic metabolism. These severe cases require surgery and intensive fluid therapy. A paradoxical aciduria may occur in cattle affected with metabolic alkalosis associated with abomasal disease. This may be due to the excretion of acid by the kidney in response to severe potassium depletion or to the excretion of acid metabolites as a result of starvation, dehydration and impaired renal function. In the experimental model in sheep, renal net acid excretion decreases and sodium excretion increases initially, followed by increased net acid excretion and decreased sodium excretion resulting in aciduria and marked sodium conservation.

Volvulus phase

Following the dilatation and displacement phase, the distended abomasum may twist in a clockwise or anticlockwise (viewed from the right side) direction in a vertical plane around a horizontal axis passing transversely across the body in the vicinity of the omasoabomasal orifice. The volvulus will usually be of the order of 180–270° and causes a syndrome of acute obstruction with local circulatory impairment and ischemic necrosis of the abomasum. Detailed examinations of necropsy specimens of volvulus of the abomasum indicate that the displacements can occur in a dual axial system. One system relates to displacements of the abomasum on a pendulum model, the point of suspension being situated on the visceral surface of the liver and the arms consisting of parts of the digestive tract adjacent to the abomasum. The other system comprises axes centered on the abomasum, about which this organ is able to rotate without changing its position in the abdomen. A theoretical analysis of the types of displacement of the abomasum that can occur is described.

In some cases the abomasum and omasum are greatly distended and form a loop with the cranial part of the duodenum. This loop may twist up to 360° in a counterclockwise direction as viewed from the rear or from the right side of the cow. The reticulum is drawn caudally on the right side of the rumen by its attachment to the fundus of the abomasum. The probable mode of rotation is in a sagittal plane. Abomasal volvulus with involvement of the omasum and reticulum
does occur but represents only about 5% of cases. Pressure and tension damage to the ventral vagal nerve trunk and to the blood vessels are in part responsible for the poor prognosis in severe cases, even after successful surgical correction.

There is speculation that violent exercise and transportation may be contributory factors in the pathogenesis of acute abomasal volvulus, which occurs occasionally in mature cows and young calves without a history of immediate previous illness associated with the dilatation phase. The metabolic changes that occur are similar to those described above.

Post-surgical complication in right-side displacement of the abomasum or abomasal volvulus

A vagus-indigestion-like syndrome may occur in cattle treated for RDA or abomasal volvulus. Possible mechanisms include vagus nerve injury, overstretching of the abomasal wall during prolonged distension resulting in neuromuscular junction alterations and autonomic motility modification, thrombosis and abomasal wall necrosis, and peritonitis.

CLINICAL FINDINGS

Dilatation and displacement phase

In right-side dilatation and displacement there is usually a history of calving within the last few weeks with inappetence and decreased milk production; the feaces are reduced in amount and are abnormal. The cow may have been treated for an uncertain disorder of the digestive tract within the last several days. Anorexia is usually complete when the abomasum is distended. There is usually depression, dehydration, no interest in feed, perhaps increased thirst and sometimes muscular weakness. Affected cows will commonly sip water continuously. The temperature is usually normal, the heart rate will vary from normal to 100/min, and the respiration are usually within the normal range. The mucous membranes are usually pale and dry. The reticulorumen is atonic and the rumen contents (the rumen pack) feel excessively doughy. The distended abomasum may be detectable as a tense viscus on palpation immediately behind and below the right costal arch. Ballottement of the middle third of the right lateral abdomen immediately behind the right costal arch along with simultaneous auscultation will reveal fluid-splashing sounds suggesting a fluid-filled viscus. In many cases the dilatation continues and after 3–4 days the abdomen is visibly distended on the right side and the abomasum can be palpated on rectal examination. It may completely fill the right lower quadrant of the abdomen and feel tense and filled with fluid and gas. Percussion and simultaneous auscultation over the right middle to upper third of the abdomen commonly elicits a characteristic high-pitched ping.

Volvulus phase

Abomasal volvulus usually develops several days after the onset of dilatation of the abomasum but it is usually not possible to distinguish precisely the stages of the disease. However, in abomasal volvulus, the clinical findings are usually much more severe than during the dilatation phase. The abdomen is visibly distended, depression and weakness are marked, dehydration is obvious, the heart rate is 100–120/min and respirations are increased. Recumbency with a grossly distended abdomen and grunting may occur and represents a poor prognosis. A rectal examination is very important at this stage. In the dilatation stage the partially distended abomasum may be palpable with the tips of the fingers in the right lower quadrant of the abdomen. It may not be palpable in large cows. In the volvulus phase, the distended tense viscus is usually palpable in the right abdomen anywhere from the upper to the lower quadrant.

The feaces are usually scant, soft and dark in color. The soft feaces must not be mistaken for diarrhea, as is commonly done by the owner of the animal. Cattle with abomasal volvulus usually become recumbent within 24 hours after the onset of the volvulus. Death usually occurs in 48–96 hours from shock and dehydration. Rupture of the abomasum may occur and cause sudden death.

Acute abomasal volvulus (adult cattle)

In acute abomasal volvulus in adult cattle there is a sudden onset of abdominal pain with kicking at the abdomen, depression of the back and crouching. The heart rate is usually increased to 100–120/min, the temperature is subnormal and there is peripheral circulatory failure. The animal feels cool and the mucous membranes are pale, dry and cool. The abdomen is grossly distended on the right side and auscultation and percussion reveal the tympanitic sounds of a gas-filled viscus. Fluid-splashing sounds are audible on percussion. Paracentesis of the distended abomasum will usually reveal large quantities of blood-tinged fluid with a pH of 2–4. The distended abomasum can usually be palpated on rectal examination but the torsion may have moved it in a cranial direction and not uncommonly these are not as readily palpable as when only dilated. The feaces are scant, soft and dark in color and become blood-stained or melenic in the ensuing 48 hours if the cow lives long enough. In some cases there is profuse watery diarrhea.

Acute abomasal volvulus (calves)

In calves with acute abomasal volvulus, there is a sudden onset of anorexia, acute abdominal pain with kicking at the belly, depression of the back, bellowing and straining. The heart rate is usually 120–160/min, the abdomen is distended and tense, and auscultation and percussion over the right abdomen reveal distinct high-pitched pings. Palpation behind the right costal arch reveals a tense viscus that is painful on even moderate palpation.

Abomasal displacement and volvulus in beef cattle

Abdominal distension, anorexia and colic are common historical findings. Clinically, there is abdominal distension, tachycardia and colic, and a high-pitched ping is audible on percussion over the right side of the abdomen. A distended gas-filled viscus is commonly palpable on rectal examination. The course of the disease in beef cattle appears to be more protracted than in dairy cattle.

Post-surgical complication in abomasal volvulus

The most frequent complication encountered following surgical correction of RDA and abomasal volvulus resembles vagus indigestion, which occurs in 14–21% of cases. The case fatality rate is high, with only 12–20% of affected animals returning to normal production. In affected cattle, there is ruminal distension, rumen hypermotility or atony, and abnormal feaces (usually scant and dry).

CLINICAL PATHOLOGY

Serum biochemistry

There are varying degrees of hemocoagulation (increased PCV and total serum proteins), metabolic alkalosis, hypochloremia and hypokalemia. The severity of volvulus can be classified, and the prognosis evaluated, according to the amount of fluid in the abomasum and the concentration of serum chloride and the heart rate:

- Group 1 – abomasum distended principally with gas
- Group 2 – abomasum distended with gas and fluid, and surgical reduction possible without removal of fluid
- Group 3 – abomasum distended with gas and fluid, 1–29 L of fluid removed before reduction of abomasum
- Group 4 – abomasum distended with gas and fluid, more than 30 L of fluid removed before reduction of torsion

The serum chloride levels and heart rates before surgery are also valuable prognostic aids. Cows classified as group 3 or 4 or those having presurgical chloride levels equal to or below 79 mEq/L (79 mmol/L)
or pulse rates of 100/min or more have a poor prognosis.

The base excess concentration of the extracellular fluid can be a useful prognostic and diagnostic indicator in cows with abomasal volvulus or right displacement of the abomasum. In one retrospective study cows with a base excess of ± 5.0 mEq/L (5.0 mmol/L) had abomasal torsion rather than displacement. The survival rate of cows with abomasal volvulus was 50% with a base excess ± 0.1 mEq/L (0.1 mmol/L), whereas it was 84% if the base excess was + 10.0 mEq/L (10.0 mmol/L).

A cross-sectional study of the serum electrolyte and mineral concentrations in dairy cows with abomasal displacement or volvulus at the time of on-farm diagnosis found lower serum calcium, phosphorus, magnesium, potassium and chloride levels and an increase in the anion gap compared to controls.

Urinalysis
Paradoxic aciduria may also be present.

Hemogram
The total and differential leukocyte count may indicate a stress reaction in the early stages, and in the later stages of volvulus there may be leukopenia with a neutropenia and degenerative left shift due to ischemic necrosis of the abomasum and early peritonitis.

Abomasocentesis
Centesis of the distended abomasum will yield large quantities of fluid without protozoa and a pH of 2-4. The fluid may be serosanguineous when volvulus is present.

PROGNOSTIC INDICATORS
Several clinical and laboratory findings have been examined as prognostic indicators of cows affected with RDA and abomasal volvulus. In one series of 458 cows with right displacement or abomasal volvulus, a decreased temperature and tachycardia when first examined indicated a poor prognosis. Using multiple logistic regression of three admission variables (heart rate, base excess and plasma chloride) and five surgical variables (heart rate, base excess, diagnosis, method of decompression and appearance of abomasal mucosa), it was possible to predict the outcomes with a high degree of accuracy. In another series of 80 cattle with abomasal volvulus, the heart rate, hydration status, period of inappetence and serum alkaline phosphatase were the best preoperative prognostic indicators. An anion gap of 30 mEq/L was indicative of a poor prognosis and was more accurate than either serum chloride or base excess values. The surgical and postoperative findings in cattle with abomasal volvulus are good prognostic indicators of outcome. Cattle with omasal–abomasal volvulus have a worse prognosis than those without omasal involvement. Large abomasal fluid volume, venous thrombosis and blue or black abomasal color before decompression are all indicative of a poor prognosis.

The evaluation of the degree of circulatory insufficiency, dehydration and levels of base excess and blood lactate are also used but are less reliable. Postoperatively decreased gastrointestinal motility is an unfavorable prognostic sign.

NECROPSY FINDINGS
In abomasal dilatation the abomasum is grossly distended with fluid and some gas. The rumen may contain an excessive amount of fluid. In some cases there may be impaction of the pylorus with particles of soil or sand and there may be an accompanying pyloric ulcer. In abomasal volvulus the abomasum is grossly distended with brownish, sanguineous fluid and is twisted usually in a clockwise direction (viewed from the right side), often with displacement of the omasum, reticulum and abomasum. In complete volvulus the wall of the abomasum is grossly hemorrhagic and gangrenous and may have ruptured.

DISEASES OF THE ABOMASUM

• Subacute abomasal ulceration with moderate dilatation of the abomasum in a recently calved cow may not be distinguishable clinically from RDA. The presence of melena suggests abomasal ulcers but these may be present as secondary complications in dilatation and RDA.

• Cecal torsion is characterized by distension of the right flank, tympanic sounds on auscultation and percussion, and the cecum can usually be palpated and identified tentatively, on rectal examination, as a long (60-80 cm), usually easily movable, cylindrical, tense tube (10-20 cm in diameter), with a blind sac.

• Fetal hydrops is characterized by bilateral distension of the lower abdomen and an enlarged gravid uterus palpable on rectal examination.

• Chronic or subacute traumatic reticuloperitonitis may resemble abomasal dilatation but in the former there may be a grunt on deep palpation, the feaces are usually firm and dry, the abdomen is gaunt and a mild fever may be present. However, a laparotomy may be necessary to make the diagnosis.

• Abomasal volvulus is characterized by abdominal distension of the right side, pings on percussion and auscultation, dehydration, weakness and shock with a heart rate up to 120/min. The distended viscus can usually be palpated in the right lower quadrant of the abdomen. It must be differentiated from the following:

  • Intestinal obstruction is characterized by a history of sudden onset of anorexia, abdominal pain, scant feaces, which may be blood-tined, and the affected portion of the intestines or loops of distended intestine may be palpable rectally.

  • Acute diffuse peritonitis as a sequel to local peritonitis in a cow soon after calving may be indistinguishable from acute abomasal volvulus. There is severe toxemia, tachycardia, dehydration, abdominal distension, grunting, weakness, recumbency and rapid death. Paracentesis of the peritoneal cavity will assist in the diagnosis.

DIFFERENTIAL DIAGNOSIS

The diagnosis and differential diagnosis of right-sided dilatation, displacement and volvulus of the abomasum is dependent on consideration of the absence or presence of pings in the right abdomen, the findings on rectal examination and the other clinical findings, including the history. Detecting a ping on percussion and auscultation of the right abdomen must be accompanied by a rectal examination to determine the presence and nature of a gas-filled viscus to account for the ping.

Dilatation and displacement of abomasum

The characteristic features of dilatation and right-sided displacement of the abomasum are recent calving, a vague indigestion since calving, soft, scant feaces, a ping over the right abdomen and the presence of the distended tense viscus in the right lower abdomen. It must be differentiated from the following:

• Impaction of the abomasum associated with vagus indigestion is characterized by an enlarged abomasum that pits on digital palpation and feels like a doughy mass behind the lower aspect of the costal arch, situated on the floor of the abdomen, whereas most cases of dilatation are situated more dorsally adjacent to the right paralumbar fossa. Pings are not present in abomasal impaction. A laparotomy may be required to distinguish between them.

Pings over the right abdomen

Diseases resulting in pings over the right abdomen include dilatation and distension of the abomasum, cecum, cranial duodenum, parts of the small intestine, descending colon and rectum and pneumatic. The evaluation of a ping is dependent upon the size of the area and location of the sound elicited by percussion and simultaneous auscultation. The common clinical characteristics of these pings are as follows:

• Dilatation and right-side displacement of the abomasum: the ping is usually audible between the ninth and 12th ribs extending from the costochondral junction of the ribs to their proximal third aspects. Rarely will the ping extend into the paralumbar fossa in right-side dilatation and displacement.
Abomasal volvulus: The area of the ping is typically larger than that of the RDA and extends more cranially and caudally, often extending into the right paralumbar fossa and not completely filling the fossa. Also, the ventral border of the ping area in an abomasal volvulus is variable, often horizontal because of the level of fluid within the abomasum.

Cecal dilatation: The ping is usually confined to the dorsal paralumbar fossa and caudal one or two intercostal spaces. In dilatation and torsion of the cecum the ping usually fills the paralumbar fossa and extends cranially and caudally the equivalent of two rib spaces. The ascending colon is often involved in a torsion of the cecum, which will result in an enlarged ping area extending from the paralumbar fossa. In dilatation of the ascending colon the ping may be centered over the proximal aspects of the 12th and 13th ribs.

Intestinal obstruction: The presence of multiple, small areas of ping that vary in pitch and intensity is characteristic of dilatation of the jejunum caused by intussusception or intestinal volvulus.

Dilatation of descending colon and rectum: A ping in the right caudal abdomen just ventral to the transverse processes of the vertebrae indicates dilatation of the descending colon and rectum, which is commonly heard following rectal examination.

Pneumoperitoneum: Pings may be audible over a wide area of the dorsal third of the abdomen bilaterally. In one study, the sensitivity and predictive values of abomasum as the source of the ping were 98% and 96% respectively; for cecum and/or ascending colon, the sensitivity and predictive values were both 87%.

The prognosis in right-side dilatation, displacement, and volvulus is favorable if the diagnosis is made within a few days after the onset of clinical signs and before large quantities of fluid accumulate in the abomasum. Slaughter for salvage may be the best course of action for cattle of commercial value. Cows with considerable economic worth can be treated as outlined here. Not all cases require surgical correction: medical treatment is possible in mild cases.

Medical therapy for mild cases

In mild cases of dilatation and minimal displacement with a mild systemic disturbance, empirical treatment with 500 mL of 25% calcium borogluconate intravenously may yield good results. The rationale for the calcium administration is to improve abomasal motility. Affected cows are also offered good-quality hay but no grain for 3-5 days and monitored daily. Surgical correction may not be necessary if the appetite and movements of the alimentary tract return to normal in a few days. The ping in the right abdomen may gradually become smaller in 2-3 days and eventually disappear.

In mild cases of dilatation with only slight hemocoagulation and metabolic alkalosis, early treatment with fluids and electrolytes intravenously and orally will often yield good results. The fluid therapy is essential to restore motility of the gastrointestinal tract, particularly the abomasum, which is distended with fluid and must begin evacuating its contents into the duodenum for absorption of the electrolytes to occur. The cow will usually not regain her appetite until the abomasal atony has been corrected.

A combination of hyoscine-buty1 bromide and dipyrone and fasting has been recommended based on field experience. Recovery occurred in about 77% of affected cows within 48 hours.

Deflation of distended abomasum in calves

Gas can be removed from a grossly distended (bloated) abomasum of calves as an emergency measure prior to surgical correction by laparotomy. The calf is placed in dorsal recumbency and the abdomen is punctured with a 16-gauge 12 cm hypodermic needle at the highest point of the distended abdomen between the umbilicus and the xiphoid. After the distension is relieved and fluid therapy is begun, the need for a laparotomy can be assessed and performed if necessary.

Surgical correction

In the more advanced cases of dilatation, displacement, and volvulus, a right flank laparotomy for drainage of the distended abomasum and correction of the volvulus if present is necessary. The surgical techniques in common use have been described. Intensive fluid therapy is usually necessary preoperatively and for several days postoperatively to correct the dehydration and metabolic alkalosis and to restore normal abomasal motility. Myographic studies of the postoperative abomasal and duodenal motility reveal loss of motility, some retrograde motility and loss of spike activity. Cholinergics have been used to help restore motility but are not reliable. Rumen transplants to restore rumen function and appetite will provide a more effective stimulus to restore gastrointestinal tract motility.

Post-surgical complications resembling a vagus-indigestion-like syndrome have been described (see under Clinical findings, above).

Fluid and electrolyte therapy

The composition of the fluids and electrolyte solutions that are indicated in RDA and abomasal volvulus has been a subject of much investigation. There are varying degrees of dehydration, metabolic alkalosis, hypochloremia and hypokalemia. With the aid of a laboratory it is possible to monitor the serum biochemistry during administration of the fluids and electrolytes and to correct certain electrolyte deficits by adding (‘spiking’) the appropriate electrolytes to the fluids. Without a laboratory, the veterinarian has no choice but to use the solutions that are considered safe and judicious.

Balanced electrolyte solutions containing sodium, chloride, potassium, calcium and a source of glucose will commonly suffice. A mixture of 2 L of isotonic saline (0.85%), 1 L of isotonic potassium chloride (1.1%) and 1 L of isotonic dextrose (5%) given at the rate of 4-6 L/h intravenously is also recommended and reliable. Experimentally induced hypochloremic, hypokalemic metabolic alkalosis in sheep has been corrected using 0.9 (300 mosmol/L), 5.6 (1200 mosmol/L) and 7.2% (2400 mosmol/L) of sodium chloride solutions given intravenously over a 2-hour period with the administered volume determined by the estimated total extracellular fluid chloride deficit. Significant difference was not found among treatments, with all solutions resulting in return of clinico-pathologic variables to pre-experimental values within 12 hours. It is suggested that rapid intravenous replacement of chloride with small volumes of hypertonic saline solution is safe and effective for correction of experimentally induced hypochloremic, hypokalemic metabolic alkalosis in sheep. Clinical trials are needed to evaluate the efficacy of hypertonic saline solution (7.2%) for the correction of naturally occurring right-side displacement and volvulus of the abomasum.

Acidifying solutions

Isotonic solutions of potassium chloride and ammonium chloride (KCl 108 g, NH₄Cl 80 g, H₂O 20 L) will provide a source of potassium and chloride and will correct the alkalosis. This solution can be given intravenously at the rate 20 L over 4 hours to a 450 kg cow. This may be followed by the use of balanced electrolyte solutions at the rate of 100-150 mL/kg BW over a 24-hour period. However, acidifying solutions such as potassium chloride and ammonium chloride must be used carefully and ideally the serum biochemistry should be monitored every hour to insure that acidosis does not occur. The above solutions are considered safe when given as described. Normal saline is also effective and potassium solutions may not be necessary unless there is severe hypokalemia.
Oral therapy

Oral electrolyte therapy has been recommended, particularly in the post-operative period following surgical drainage of the distended abomasum. A mixture of sodium chloride (50–100 g), potassium chloride (50 g) and ammonium chloride (50–100 g) is given orally daily postoperatively along with the parenteral fluids as necessary. Treatment with potassium chloride (50 g/day) orally can be continued daily until the cow resumes her normal appetite.

CONTROL

No reliable information is available on the control of right-side dilatation, displacement and volvulus of the abomasum. Because its pathogenetic mechanism is similar to LDA it would seem rational to recommend feeding programs that are used for the control of LDA.

REVIEW LITERATURE

DIETARY ABOMASAL IMPACTION IN CATTLE

Dietary abomasal impaction occurs in cattle in the prairie provinces of western Canada during the cold winter months, and elsewhere with similar circumstances, when the animals are fed poor-quality roughage. The disease is most common in pregnant beef cattle which increase their feed intake during extremely cold weather in an attempt to meet the increased needs of a higher metabolic rate.1 The disease has also occurred in feedlot cattle fed a variety of mixed rations containing chopped or ground roughage (straw, hay) and cereal grains and in late pregnant dairy cows on similar feeds.

ETIOLOGY AND EPIDEMIOLOGY

The consumption of excessive quantities of poor-quality roughage which are low in both digestible protein and energy is the primary cause.1 Impaction of the abomasum with sand can also occur in cattle if they are fed hay on sandy soils or root crops that are sandy or dirty.2 Outbreaks of impaction with sand have occurred in which up to 10% of cattle at risk were affected.

The disease occurs most commonly in young pregnant beef cows that are kept outdoors year-round, including during the cold winter months, when they are fed roughages consisting of either grass or legume hay or cereal straw, which may or may not be supplemented with some grain. In these circumstances cows commonly lose 10–15% of their total body weight from October to May and even more during very cold winters. In one retrospective study of the necropsy reports of cattle that died with abomasal impaction, 20% of the animals had lesions of traumatic reticuloperitonitis, 60% were thought to be due to the ingestion of too much poor-quality roughage without a supplement of concentrate, and 20% did not fit into either category.3

When large quantities of long roughage without sufficient grain are fed during very cold weather, the cattle cannot eat sufficient feed to satisfy energy needs, so that the roughage is then provided in a chopped form. The chopped roughage is commonly mixed with some grain in a mix mill but usually at an insufficient level to meet the energy requirements. Cattle can and do eat more of these chopped roughage–grain mixtures than of long roughage because the smaller particles pass through the forestomachs at a more rapid rate. But impaction of the abomasum, omasum and rumen may occur because of the relative indigestibility of the roughage. Outbreaks may occur affecting up to 15% of all pregnant cattle on individual farms when the ambient temperature drops to -5 to -10°C (14 to -22°F) for several days.

Omasal and abomasal impaction has occurred in a group of beef suckler cows in late gestation housed in straw yards and fed solely on pea haulm.4 The disease has also occurred in feedlot cattle fed similar rations (e.g. 80% roughage, 20% grain) in an attempt to reduce the high cost of grain feeding and to satisfy beef grading standards that put the emphasis on producing a smaller amount of fat cover. With these constraints and the increased emphasis on roughage feeding, it is possible that the incidence of abomasal impaction may increase in feedlot cattle. The feeding of almond shells to dairy replacement heifers has also resulted in abomasal impaction.5

The ingestion of gravel (stones) by dairy cattle kept in dry-lot facilities can result in complete, nonstrangulating intraluminal obstruction of the abomasum and duodenum.6 The gravel, consisting of sand and small stones, may be inadvertently mixed with the feed when it is being scraped from bunker silos. It is also possible that some cows may ingest the gravel through pica.

PATHOGENESIS

Chopped roughage and finely ground feeds pass through the forestomachs of ruminants more quickly than long roughage and perhaps in this situation the combination of low digestibility and excessive intake leads to excessive accumulation in the forestomachs and abomasum.

When large quantities of sand are ingested, the omasum, abomasum, large intestine and cecum can become impacted. The sand that accumulates in the abomasum causes abomasal atony and chronic dilatation.

Once impaction of the abomasum occurs, a state of subacute obstruction of the upper alimentary tract develops. The hydrogen and chloride ions are continually secreted into the abomasum in spite of the impaction and atony and an alkalosis with hypochloremia results. Varying degrees of dehydration occur because fluids are not moving beyond the abomasum into the duodenum for absorption. Potassium ions are also sequestered in the abomasum, resulting...
in a hypokalemia. Almost no ingesta or fluids move beyond the pylorus, and dehydration, alkalosis, electrolyte imbalance and progressive starvation occur. The impaction of the abomasum is usually severe enough to cause permanent abomasal atony.

**CLINICAL FINDINGS**

Complete anorexia, scant feces and moderate distension of the abdomen are the usual presenting complaints given by the owner. The onset is usually slow and progressive over a period of several days. Cattle that have been affected for several days have lost considerable weight and are too weak to rise. The body temperature is usually normal but may be subnormal during cold weather, which suggests that the specific dynamic action of the rumen is not sufficient to meet the energy needs of basal metabolism. The heart rate varies from normal to 90–100/min and may increase to 120/min in advanced cases where alkalosis, hypochloremia and dehydration are marked. The respiratory rate is commonly increased and an expiratory grunt due to the abdominal distension may be audible, especially in recumbent cattle. A mucoid nasal discharge usually collects on the external nares and muzzle, which is usually dry and cracking because of the failure of the animal to lick its nostrils and the effects of the dehydration.

The rumen is usually static and full of dry rumen contents, or it may contain an excessive quantity of fluid in those cattle that have been fed finely ground feed. The pH of the ruminal fluid is usually within the normal range (6.5–7.0). The rumen protozoan activity ranges from normal to a marked reduction in numbers and activity as assessed on a low-power field. The impacted abomasum is usually situated in the right lower quadrant of the abdomen on the floor of the abdominal wall. It usually extends caudally beyond the right costal arch but may or may not be easily palpable because of the gravid uterus, but an impacted omasum may also be palpable. It may be impossible, however, to distinguish between an impacted abomasum and an impacted omasum. In feedlot steers and non-pregnant heifers the impacted abomasum and omasum may be easily palpable on rectal examination. Deep palpation and strong percussion of the right flank may elicit a "grunt" as is common in acute traumatic reticuloenteritis, and this is probably due to overdistension of the abomasum and stretching of its serosa.

The course of the disease depends on the extent of the impaction when the animal is first examined and the severity of the acid-base and electrolyte imbalances. Severe affected cattle die in 3–6 days after the onset of signs. Rupture of the abomasum has occurred in some cases and death from acute diffuse peritonitis and shock occurs precipitously in a few hours. In sand impaction, there is considerable weight loss, chronic diarrhea with sand in the feces, weakness, recumbency and death within a few weeks.

Severe impaction and distension of the rumen and the abomasum can occur in cattle given access to large quantities of finely chopped straw during the cold winter months. There is gross distension of the abdomen, anorexia, scant dry feces, and affected animals will drop large, dry, fibrous cuds. The rumen is grossly distended and usually static.

Cows fed solely on pea haulm are dull and anorectic with grossly distended abdomens and varying degrees of bloat. Cattle with obstruction of the abomasum and duodenum with gravel are anorexic, depressed and weak. The abdomen may be distended and rumen hypomotility or atony is present. The feces are scant. The obstruction cannot usually be felt on rectal examination and a right flank laparotomy is necessary to make the diagnosis. A marked hypochloremic, hypokalemic metabolic alkalosis is characteristic.

**CLINICAL PATHOLOGY**

A metabolic alkalosis, hypochloremia, hypokalemia, hemococoncentration and a total and differential leukocyte count within the normal range are common.

**NECROPSY FINDINGS**

At necropsy the abomasum is commonly grossly enlarged to up to twice normal size and impacted with dry rumen-like contents. The omasum may be similarly enlarged and impacted with the same contents as in the abomasum. The rumen is usually grossly enlarged and filled with dry ruminal contents or ruminal fluid. The intestinal tract beyond the pylorus is characteristically empty and has a dry appearance. Varying degrees of dehydration and emaciation are also present. If rupture of the abomasum occurs, lesions of acute diffuse peritonitis are present. Abomasal tears, ulcers, and necrosis of the walls of the rumen, omasum or abomasum may occur.

**DIFFERENTIAL DIAGNOSIS**

The clinical diagnosis of impacted abomasum depends on the nutritional history, the clinical evidence of impaction of the abomasum and the laboratory results. The disease must be differentiated from abomasal impaction as a complication of vagus indigestion, omasal impaction, diffuse peritonitis and acute intestinal obstruction due to intestinal accidents or enteroliths and lipomas.

- **Impaction of the abomasum as a complication of traumatic reticuloenteritis** usually occurs in late pregnancy, commonly only in one animal; a mild fever may or may not be present and there may be a grunt on deep palpation of the xiphoid. The rumen is usually enlarged and may be atonic or hypermotile. Depending on the lesion present a neutrophilia may be present, suggestive of a chronic infection. A hypochloremia is common, as in dietary impaction. In many cases it is impossible to distinguish between the two causes of impacted abomasum and a laparotomy may be necessary to explore the abdomen for evidence of peritoneal lesions. Cattle with abomasal impaction as a complication of traumatic reticuloenteritis are usually a single incident and have usually been ill for several days, whereas those with dietary impaction have usually been ill for only a few days and more than one may be affected.

- **Impaction of the omasum** occurs in advanced pregnancy and is characterized by anorexia, scant feces, normal rumen movements, moderate dehydration and an enlarged omasum that may be palpable per rectum or behind the right costal arch. The serum electrolytes may be within normal limits if the abomasum is normal but hypochloremia and hypokalemia are present. Fibrinous adhesions may be palpable on rectal examination, and peritonitis may result in some diagnostic peritoneal exudate, but a negative result cannot rule out peritonitis. The presence of a marked leukopenia and neutropenia or a neutrophilia may assist in the diagnosis, but it is often necessary to perform an exploratory laparotomy to confirm the diagnosis.

- **Intestinal obstructions** due to intestinal accidents or enteroliths result in anorexia, scant feces, dehydration and abdominal pain, and the abnormality may be palpable on rectal examination. The rumen is usually static and filled with dry contents. Fluid and gas accumulations in the intestines anterior to the obstruction may be detectable as fluid-splashing sounds by using simultaneous auscultation and succussion of the abdomen.

**TREATMENT**

Salvage or treatment?

The challenge in treatment is to be able to recognize the cases that will respond to treatment and those that will not and should therefore be slaughtered immediately for salvage. Those that have a severely impacted abomasum or are weak with a marked tachycardia (100–120/min) are poor treatment risks.
and should be slaughtered. Rational treatment would appear to consist of correcting the metabolic alkalosis, hypochloremia, hypokalemia and dehydration and attempting to move the impacted material with lubricants and cathartics, or surgically emptying the abomasum. Balanced electrolyte solutions are infused intravenously on a continuous basis for up to 72 hours at a rate of 100–150 mL/kg BW over a 24-hour period. Some cases will respond remarkably well to this fluid therapy and begin ruminating and passing feces in 48 hours. The use of acidifying isotonic solutions of mixtures of ammonium chloride and potassium chloride at a rate of 20 L per 24-hour period for a 450 kg animal as described under the treatment for RDA is also recommended.

Dioctyl sodium sulfosuccinate is administered into the rumen by stomach tube at a dose rate of 120–180 mL of a 25% solution for a 450 kg animal repeated daily for 3–5 days. It is mixed with 10 L of warm water and 10 L of mineral oil. The amount of mineral oil can then be increased to 15 L/d after the third day and for a few days until recovery is apparent. A beneficial response cannot be expected in less than 24 hours and most cattle that do respond will show improvement by the end of the third day after treatment begins. Cholinergics such as neostigmine, phystostigmine and carbamylcholine have been used but appear not to alter the outcome.

**Surgery**

Surgical correction consists of an abomasotomy through a right paralumbar approach and removal of the contents of the abomasum. The results are often unsuccessful, probably because of abomasal atony that exists and that appears to worsen following surgery.7 An alternative approach may be to do a rumenotomy, empty the rumen and infuse dioctyl sodium sulfosuccinate directly into the abomasum through the reticulo-omental orifice in an attempt to soften and promote the evacuation of the contents of the abomasum. The placement of a nasogastric tube into the omasal groove and into the abomasum through a rumenotomy procedure is described. Mineral oil can then be pumped into the abomasum at the rate of 2 L/day for several days. Recovery should occur within 5–7 days. A rumenotomy and emptying of the rumen is necessary in the case of severe straw impaction of the rumen.

The induction of parturition using 20 mg of dexamethasone intramuscularly may be indicated in affected cattle that are within 2 weeks of term and in which the response to a few days' treatment has been unsuccessful. Parturition may assist recovery as a result of a reduction in intra-abdominal volume. In sand impaction, affected cattle should be moved off the sandy soil and fed good hay and a grass mixture containing molasses and minerals. Severely affected cattle should be treated with large daily doses of mineral oil – at least 15 L/d.

**Gravel obstruction of the abomasum and duodenum** can be corrected surgically by right flank laparotomy.5

**CONTROL**

**Provision of nutrient requirements during cold weather**

Prevention of the disease is possible by providing the necessary nutrient requirements for wintering pregnant beef cattle with added allowances for cold windy weather when energy needs for maintenance are increased. When low-quality roughage is to be used for wintering pregnant beef cattle, it should be analyzed for crude protein and digestible energy. Based on the analysis, grain is usually added to the ration to meet the energy and protein requirements.2 Pregnant beef cows fed a diet of 94% barley straw for 83 days during the cold winter months may consume only 70% of their energy requirements. Such straw-based diets must be supplemented with protein and energy.3 During prolonged periods of cold weather, wintering pregnant beef cattle should be given additional amounts of feed to meet the increased feed requirement for maintenance, which has been estimated to be 30–40% greater during the colder months than during the warmer months. These increased requirements are due almost equally to the effects of reduced feed digestibility and the increased maintenance requirements.5

**Nutrient requirements for beef cattle**

The published nutrient requirements of beef cattle are guidelines for the nutrition of cattle under average conditions and higher nutrient levels than those indicated may be necessary to provide for maintenance requirements, particularly during periods of cold stress.7 Adequate amounts of fresh drinking water should be supplied at all times and the practice of forcing wintering cows to obtain their water requirements from eating snow while on low-quality roughage is extremely hazardous. The question of whether or not low-quality roughages should be chopped or ground for wintering pregnant beef cattle is controversial. The daily voluntary intake of low-quality roughage can be increased by chopping or grinding but neither processing method increases quality or digestibility; in fact digestibility is usually decreased. If increased consumption during cold weather exceeds physical capacity and the nutrient requirements are still not satisfied, impaction of the abomasum may occur. Thus during the coldest period of the winter low-quality roughages must be supplemented with concentrated sources of energy such as cereal grains.8

**Avoid excessive fiber**

Omasal and abomasal impaction due to the provision of excessive poor-quality roughage is preventable by supplementation with appropriate sources of energy and protein.

**REFERENCES**

**ABOMASAL IMPACTION IN SHEEP**

Abomasal dilatation and impaction in sheep as a result of an emptying defect has been reported in Suffolk sheep1 and in the Dorset breed.2 Affected sheep are ewes, usually 2–6 years of age and in late gestation or recently lambed. The duration of illness varies from several days to a few months and affected animals may become emaciated. The diets fed to affected animals consisted of grain and good-quality hay. Rams have also been affected. Clinically, they are characterized by progressive weight loss, anorexia, variable degrees of distension of the right lower abdomen, palpable masses in the right lower abdomen, increased concentrations of rumen chloride and a grossly enlarged and impacted abomasum.3 Hypochloremia, hypokalemia and metabolic alkalosis are common1 and ruminal chloride levels are increased up to 38.5 mmol/L, suggesting reflux from the abomasum.4 Treatment has been ineffective and the case fatality rate may exceed 90%. At necropsy, the abomasum is grossly enlarged and commonly contains rumenlike contents, which are dry and doughy. In some cases the abomasum contains an excessive quantity of fluid.

There is a report of abomasal impaction with anorexia causing high mortality in young lambs.7 Affected lambs developed anorexia, dullness and reluctance to walk. Sudden death occurred in lambs less than
ABOMASAL PHYTOBEOZARS AND TRICHOBEOZARS

A velvety form of abomasal phytobezoar occurs in goats and sheep in the arid regions of southern Africa and causes significant economic loss. The composition of the bezoars resembles that of pappus hairs and stems of the Karoo bushes. They have a striking velvety appearance. Phytobezoars have been experimentally reproduced in goats and sheep by feeding the mature flowers or seeds and pappus hairs of Karoo bushes.

Rumenobomasal lesions have been reported to occur in steers 20–24 months of age with a history of inappetence and weight loss, and licking their own and other animals’ haircoat. Numerous hairs (0.5–1.5 cm in length) were found implanted in the abomasal mucosa, especially in the region of the torus pyloricus. Areas of hair implantation were frequently accompanied by scattered and severe abomasitis, erosions and ulcers. Thickening of the rugae and plicae of the pylorus was present. In the rumen, rumenitis and hyperkeratosis, characterized by short, reddish edematous ruminal papillae containing small numbers of trapped hairs, were present. The severity of the lesions increased with the number of hairs implanted in the mucosa.

REFERENCES

ABOMASAL ULCERS OF CATTLE

Abomasal ulceration occurs in mature cattle and calves and may cause acute abomasal hemorrhage with indigestion, melena and sometimes perforation, resulting in a painful acute local peritonitis or acute diffuse peritonitis and rapid death, or a chronic indigestion with only minimal abomasal hemorrhage. Some calves have abomasal ulceration at necropsy or slaughter that was subclinical.

ETIOLOGY
Primary ulceration
While many different causes of primary abomasal ulceration have been suggested the cause is unknown. Possible causes that have been considered but for which there is no reliable evidence of a cause and effect relationship include:
- Abomasal hyperacidity in adult cattle – but there is no direct evidence to support the hypothesis
- Mechanical abrasion of the pyloric antrum due to the ingestion of coarse roughage, such as straw, or the presence of trichobezoars
- Bacterial infections such as Clostridium perfringens type A or unidentified fungi
- Trace mineral deficiencies such as copper deficiency
- Concurrent stress as in cattle with severe inflammatory processes or in severe pain
- Abomasal hyperacidity in calves nursing their dams or calves hand-fed milk or milk replacers has also been proposed as a cause of primary ulceration1 but there is no direct evidence.

Secondary ulceration
Abomasal ulceration secondary to other diseases occurs. Examples include lymphoma of the abomasum and erosions of the abomasal mucosa in viral diseases such as bovine virus diarrhea, rinderpest and bovine malignant catarrh.

EPIDEMIOLOGY
Primary abomasal ulcers
Primary abomasal ulcers occur in lactating dairy cows, mature bulls, hand-fed calves, veal calves and sucking beef calves. The epidemiological circumstances for each of these groups are presented here.

Lactating dairy cows
Some observations have found that acute hemorrhagic abomasal ulcers occur in high-producing mature dairy cows in early lactation, while others have found that most acute bleeding ulcers occurred in cows 3–6 months after parturition. The close relationship of the disease to parturition suggests that a combination of the stress of parturition, the onset of lactation and high-level grain feeding is associated with acute ulceration in dairy cows.

However, epidemiological observations of acute hemorrhagic abomasal ulceration in cattle have found no association with the stress of calving. The incidence was highest in dairy cows during the summer months when the animals were grazing on pasture. There was also a direct association between amount of rainfall, amount of fertilizer used, and stocking rate, and the amount of milk produced by affected cows. This suggests that some factor in grass may be a risk factor in the acute disease in mature dairy cattle.

Mature high-producing dairy cows in early lactation may develop acute hemorrhagic ulceration of the abomasum following a prolonged illness such as pneumonia or after having been to a cattle show and sale. This suggests that stress may be an important contributing cause.

The prevalence of abomasal ulcers in mature cattle varies depending on the population of animals surveyed. Of cattle admitted to a veterinary teaching hospital over a 4-year period, 2.17% had confirmed abomasal ulcers. In surveys at abattoirs the prevalence may reach 6%. The case fatality rate for mature cattle with confirmed abomasal ulcers is about 50%, for those with severe blood loss or diffuse peritonitis the case fatality rate is usually 100%. Type 1 nonperforating abomasal ulcers were found in 21% of cows examined at the abattoir and there was no clinical evidence of the ulcers before slaughter, but 32% of the animals were anemic and 44% were hyperproteinemic, which could be expected in cattle with chronic blood loss.

Mature bulls and feedlot cattle
Acute bleeding ulcers occur occasionally in mature dairy and beef bulls, particularly...
following long transportation, prolonged surgical procedures and in painful conditions such as a fractured limb or rupture of the cruciate ligaments of the stifles joint. Abomasal ulcers have also been the cause of sudden death in yearling feedlot cattle. Examination of a random sample of the abomasa of feedlot cattle revealed that erosions were present in up to 33% of the animals, depending on their origin. It is hypothesized that the feeding of high levels of grain in feedlot cattle may be a risk factor associated with abomasal erosions.

Hand-fed calves
Ulcers of the abomasum are common in hand-fed calves when they are weaned from milk or milk replacer and begin consuming roughage. The causes of the acute ulceration are unknown but by association it appears that some calves are susceptible when they are changing from a diet of low dry matter content (milk or milk replacer) to one of a higher dry matter content (grass, hay, grain). Most of these ulcers are subclinical and nonhemorrhagic. The incidence of abomasal ulcers in milk-fed veal calves is higher when the animals have access to roughage than when roughage is not provided. The type of roughage may also be a factor: pellets produced from corn silage were associated with more lesions than pellets produced from barley straw or alfalfa hay. Occasionally, milk-fed calves under 2 weeks of age are affected by acute hemorrhagic abomasal ulcers, which may perforate and cause rapid death.

Perforating abomasal ulcers have occurred in calves up to 6 months of age, with the majority between 6 and 12 weeks of age. Left-side displacement of the abomasum was present in 70% of the cases.

Veal calves
Abomasal ulceration is a common finding in veal calves slaughtered at 3–5 months of age. The incidence and severity of lesions are greatest in loose-housed calves with access to straw and fed milk substitute ad libitum. There was no evidence that erosions and ulcers found in the majority of veal calves affected their growth rate or welfare. No relationship was found between the presence of abomasal erosions and ulcers and the behavior of crated veal calves fed milk for 22–24 weeks.

Sucking beef calves
Well-nourished sucking beef calves, 2–4 months of age, may be affected by acute hemorrhagic and perforating abomasal ulcers while they are on summer pasture. Abomasal trichobezoars are commonly present in these calves, but whether the hair balls initiated the ulcers or developed after the ulcers is uncertain.

Abomasal ulcers and abomasal tympany occur in range beef calves from 3–12 weeks of age in beef herds in the north central region of the USA, along the eastern slopes of the Rocky Mountains and in Alberta.

In a retrospective study of 46 abomasotomies in young beef calves in western Canada, in affected herds the average incidence was 1.0% with a range among herds from 0.2–5.7%. In 80% of surgeries of the abomasum, abomasal ulcers were found, and hairballs were present in the abomasum of 76%, but this does not necessarily mean that hairballs are a causative agent (see below). Calves housed in pens or on stubble fields were nearly three times as likely to receive surgery for abomasal disease than those kept on pasture.

On-farm investigations of western Canadian beef herds that had reported abomasal ulcers in calves found that the average number of suspected and confirmed cases of fatal abomasal ulcers were 2.4 and 1.9 per farm, respectively. Most producers reported that the affected calves had died without exhibiting any clinical signs and that the affected calves were average or above average in growth performance. Most (85.6%) of the ulcers occurred in calves under 2 months of age. Most (93.3%) of the fatal ulcers were perforating, the remainder (6.7%) were hemorrhagic ulcers. The peak number of cases occurred in April and May but this seasonal incidence reflects the age structure of the calf population in Canada, where most beef calves are born during the late winter and early spring months. There was no sex predilection and no evidence of breed predisposition. There was no evidence to suggest that C. perfringens type A, Helicobacter pylori or Campylobacter spp. were involved in ulcer formation.

The relationship between the abomasal hairballs and perforating abomasal ulcers in unweaned beef calves under 4 months of age has been examined. For many years it was thought that the presence of hairballs in the abomasum abraded the mucosa, initiating an ulcerogenic process, eventually culminating in a perforating ulcer. However, finding hairballs in the abomasum of nursing beef calves with perforating ulcers does not necessarily mean that the hairballs caused the ulcer. Hairballs are present in the abomasum of the same class of calves that die from other diseases unrelated to the abomasum. Calves under 1 month of age dying of an ulcer were almost four times more likely to have an abomasal hairball than were calves dying of all other diseases. But this relationship did not exist in older calves over 30 days of age, in which about 60% of all calves, regardless of the cause of death, had an abomasal hairball. The prevalence of hairballs in the young and old ulcer calves was 57.7% and 56.7%, respectively; in the old nonulcer calves it was 63.3%. The prevalence of hairballs in the young nonulcer calves was 20.1%.

Two factors may account for the lower prevalence in young nonulcer calves. First, more than half (55%) of the nonulcer calves died in the first few weeks of life, compared with only 12.5% of the ulcer calves. Thus calves in the ulcer group had more time to develop an abomasal hairball. Second, the majority (68%) of the calves died of enteritis and sepsis, making them less likely to engage in normal nursing behavior, which involves muzzling and licking the udder, resulting in the ingestion of hair. Only 57% of calves dying of perforating ulcer had a hairball, indicating that the hairballs are not necessary for an ulcer to develop. This is supported by field observations of pathologists, who report that only 25% of calves with a perforating ulcer had an abomasal hairball. Another argument against the hairball theory is that 89% of perforations occurred in the body of the abomasum, a region that has a poorly developed musculature and is incapable of producing strong peristaltic contractions. It is suggested that the weak frictional forces generated in this region could exert an abrasive action upon the mucosal surfaces. In summary, it is suggested that abomasal hairballs are not necessary for abomasal ulcers to develop in nursing beef calves.

Dietary factors in calves fed milk or milk replacer
The cause of the high prevalence of abomasal ulceration in nursing beef calves is unknown. A low abomasal luminal pH due to the diet has been proposed as a possible factor. Experimentally, feeding dairy calves (17 days of age) cow's whole milk, resulted in lower abomasal luminal pH compared to the feeding of two different milk replacers (an all milk protein or combined milk and soy protein milk replacer). It has been hypothesized that the sucking of cow's whole milk results in a lower mean abomasal luminal pH and, because fasting or infrequent sucking of milk replacer results in a sustained period of low abomasal luminal pH, this may provide evidence for primary abomasal ulceration in nursing beef calves. This may be related to the occurrence of abomasal ulceration in nursing beef calves after a period of
inclement weather, during which time the frequency of nursing may be decreased. Captive white-tailed deer
Abomasal ulceration has been described in 32 of 200 captive white-tailed deer examined by necropsy over a period of 3.5 years.\(^{14}\) Ulceration was most common in the abomasal pylorus and at the abomasal–duodenal junction. All deer had intercurrent disease, including bacterial pneumonia, enterocolitis, intussusception, chronic diarrhea, capture myopathy and experimentally induced tuberculosis. The anatomical distribution of abomasal ulcers resembled that seen in veal calves.

**Secondary abomasal ulcers**
Abomasal ulcers occur secondary to left- and right-side abomasal displacements, abomasal impaction or volvulus, lymphomatosis and vagus indigestion, or unrelated to other diseases.

**PATHOGENESIS**
Any injury to the gastric mucosa allows diffusion of hydrogen ions from the lumen into the tissues of the mucosa and also permits diffusion of pepsin into the different layers of the mucosa, resulting in further damage. There may be only one large ulcer but more commonly there is evidence of numerous acute and chronic ulcers. A classification of abomasal ulcers in cattle is as follows.

**Type 1: Nonperforating ulcer**
There is incomplete penetration of the abomasal wall resulting in a minimal degree of intraluminal hemorrhage, focal abomasal thickening, or local serositis. Nonbleeding chronic ulcers commonly cause a chronic gastritis.

**Type 2: Ulcer causing severe blood loss**
There is penetration of the wall of a major abomasal vessel, usually in the submucosa, resulting in severe intraluminal hemorrhage and anemia. In acute ulceration with erosion of a blood vessel there is acute gastric hemorrhage with reflex spasm of the pylorus and accumulation of fluid in the abomasum, resulting in distension, metabolic alkalosis, hypochloremia, hypokalemia and hemorrhagic anemia. Usually within 24 hours there is release of some of the abomasal contents into the intestine, resulting in melena. The ruminal chloride level may increase in about 40% of cows with bleeding ulcers, which suggests abomasal reflux of acid into the rumen.\(^{15}\)

Plasma gastrin activity increases significantly in cattle with bleeding abomasal ulcers.\(^ {15}\)

**Type 3: Perforating ulcer with acute, local perforitis**
There is penetration of the full thickness of the abomasal wall, resulting in leakage of abomasal contents. Resulting perforitis is localized to the region of the perforation by adhesion of the involved portion of abomasum to adjacent viscera, omentum or the peritoneal surface. Omental bursitis and empyema may develop, with the accumulation of a large quantity of exudate and necrotic debris in the omental cavity.

Abomasal–pleural fistula associated with cranial displacement of the abomasum and abomasal ulceration has been described in a 11-month-old bull.\(^ {17}\)

**Type 4: Perforating ulcer with diffuse perforitis**
There is penetration of the full thickness of the abomasal wall, resulting in leakage of abomasal contents. Resulting perforitis is not localized to the region of the perforation; thus digesta is spread throughout the peritoneal cavity.

In nursing beef calves, about 90% of perforated abomasal ulcers occur in the body of the abomasum, with a propensity for the greater curvature.\(^ {12}\)

In some calves the ulcers are subclinical and the factors that determine how large or how deep an ulcer will become are unknown. Based on abattoir studies it is evident that abomasal ulcers will heal by scar formation.

**CLINICAL FINDINGS**
The clinical syndrome varies depending on whether ulceration is complicated by hemorrhage or perforation. The important clinical findings of hemorrhagic abomasal ulcers in cattle are abdominal pain, melena and pale mucous membranes. At least one of these clinical findings is present in about 70% of cattle with abomasal ulcers. The case fatality rates for cattle with types 1, 2, 3 or 4 are 25, 100, 50 and 100%, respectively. In the common clinical form of bleeding abomasal ulcers there is a sudden onset of anorexia, mild abdominal pain, tachycardia (90–100/min), severely depressed milk production and melena. Acute hemorrhage may be severe enough to cause death in less than 24 hours. More commonly there is subacute blood loss over a period of a few days with the development of hemorrhagic anemia. The feces are usually scant, black and tarry. There are occasional bouts of diarrhea. Melena may be present for 4–6 days, after which time the cow usually begins to recover or lapses into a stage of chronic ulceration without evidence of hemorrhage.

Melena is almost a pathognomonic sign of an acute bleeding ulcer of the abomasum. However, the presence of normal-colored feces does not preclude the presence of chronic nonbleeding ulcers, which may be the cause of an intractable indigestion. The use of an occult blood test on the feces will aid in differentiating those that are equivocal. Abomasal ulceration secondary to lymphoma of the abomasum is characterized by chronic diarrhea and melena. The ulcer does not heal.

In some cases the abomasum is grossly distended and fluid-splitting sounds are audible on auscultation similar to those in RDA. Moderate dehydration is common and affected cows commonly sip water continuously and grind their teeth frequently.\(^ {18}\) The prognosis in chronic ulceration is poor because of the presence of several ulcers and the development of chronic abomasal atony. Some cows improve temporarily but relapse several days later and fail to recover permanently. Duodenal ulceration and abdominal abscesses have also been described.\(^ {18}\)

**Perforation of ulcer**
Perforation of an ulcer is usually followed by acute local perforitis unless the abomasum is full and ruptures, when acute diffuse perforitis and shock result in death in a few hours. With the development of local perforitis, with or without omental adhesions, there is a chronic illness accompanied by a fluctuating fever, anorexia and intermittent diarrhea. This is common in dairy cows in the immediate postpartum period. Pain may be detectable on deep palpation of the abdomen and the distended, fluid-filled abomasum may be palpable behind the right costal arch. Periabomasal abscess formation from a perforated ulcer also occurs and is similar to local perforitis.

In calves with a perforated abomasal ulcer, abdominal distension and abdominal pain are common.\(^ {7}\) Perforation of an abomasal ulcer and the development of an abomasal–pleural fistula has been described in an 11-month-old bull,\(^ {17}\) Pleuritis, pericarditis, unilateral pneumothorax and pulmonary abscession were present.

**Nursing beef calves**
Calves with abomasal ulceration may have a distended gas-filled and fluid-filled abomasum that is palpable behind the right costal arch. Deep palpation may reveal abdominal pain associated with local perforitis due to a perforated ulcer. Unless an abomasal ulcer has extended to the serosa it is unlikely that it can be detected by deep palpation. Many cases of abomasal ulcers, particularly in calves, cause no apparent illness.

**CLINICAL PATHOLOGY**

**Melena**
The dark brown to black color of the feces is usually sufficient indication of gastric
hemorrhage but tests for occult blood may be necessary. Results from experiments simulating abomasal hemorrhage indicate that the transit time for blood to move from the abomasum to the rectum ranges from 7–19 hours. The available fecal occult blood tests may not detect slow abomasal hemorrhage at any one sampling. This can be overcome by testing several fecal samples over a 2–4 day period and reading multiple smears per specimen. The sensitivity of the occult blood tests increases after the fecal samples have been stored at room temperature for 2 days. The predictive value of the occult blood test may be a more reliable diagnostic indicator of abomasal disease than abdominal pain or the presence of anemia. When perforation has occurred, with acute local peritonitis, there is neutrophilia with a regenerative left shift for a few days, after which time the total leukocyte and differential count may be normal.

**Hemogram**
In acute gastric hemorrhage there is acute hemorrhagic anemia.

**Plasma gastrin activity**
Plasma gastrin concentration increases significantly in cattle with bleeding abomasal ulcers. The mean plasma gastrin concentration in healthy cattle was 103.2 pg/mL; in cattle with bleeding abomasal ulcers the mean was 1213 pg/mL.

**NECROPSY FINDINGS**
Ulceration is most common along the greater curvature of the abomasum. There is a distinct preference for most of the ulcers to occur on the most ventral part of the fundic region with a few on the border between the fundic and pyloric regions. The ulcers are usually deep and well defined but may be filled with blood clot or necrotic material and often contain fungal mycelia, which may be of etiological significance in calves. The ulcers will measure from a few millimeters to 5 cm in diameter and are either round or oval with the longest dimension usually parallel to the long axis of the abomasum. In bleeding ulcers the affected artery is usually visible after the ulcer is cleaned out.

Most cases of perforation in cattle are walled off by omentum, with the formation of a large cavity 12–15 cm in diameter in the mesentery cavity that contains degenerated blood and necrotic debris. Material from this cavity may infiltrate widely through the omental fat. Adhesions may form between the ulcer and surrounding organs or the abdominal wall (omental bursitis and omental emphysema). Multiple phytobezoars are commonly present in the abomasum of beef calves with abomasal ulcers. The mucosal changes associated with abomasal ulceration in veal calves reveal an increase in the depth of the mucosa with a loss of mucus in the region of erosions and ulcers.

Abomasal ulcers in captive white-tailed deer were characterized by focal to multifocal, sharply demarcated areas of coagulation necrosis and hemorrhage extending through the mucosa, with fibrin thrombi in mucosal blood vessels of small diameter. Visible bacteria were not associated with ulcerative lesions.

**Differential Diagnosis**
- Acute abomasal ulceration in mature cattle is characterized by abdominal pain, melena and pallor. The melena may not be evident for 18–24 hours after the onset of hemorrhage. Examination of the right abdomen may reveal a distended abomasum and a grunt on deep palpation over the abomasum, caudal to the xiphoid sternum on the right side. Tachycardia is common.
- Duodenal ulceration may cause melena and a syndrome indistinguishable from hemorrhagic abomasal ulceration.
- Chronic abomasal ulceration in mature cattle is difficult to diagnose clinically if the hemorrhage is insufficient to result in melena. The clinical findings of chronic ulceration are similar to several other diseases of the forestomach and abomasum of mature cattle. An illness of several days duration with inappetence, ruminal hypotonicity, scant feces and dehydration are common to many of these diseases. The presence of occult blood in the feces of hemorrhagic anemia suggests ulceration. The hemorrhage may be intermittent and repeated fecal tests for occult blood may be necessary. A positive result for occult blood may also be due to abomasal volvulus, intestinal obstruction or blood-sucking helminths.
- Abomasal ulceration with perforation and local peritonitis is indistinguishable from acute traumatic reticuloenteritis unless hemorrhage and melena occur. However, the abdominal pain elicited on deep palpation is most intense over the right lower abdomen and lateral aspect of the right lower thoracic wall.
- Abomasal ulceration with perforation in sucking beef calves is characterized by sudden onset of weakness, collapse, moderate abdominal distension shock and rapid death. It must be differentiated from other causes of diffuse peritonitis and intestinal obstruction.
- Chronic abomasal ulceration in sucking beef calves associated with hair balls and chronic abomasitis from eating sand and dirt cannot usually be diagnosed as a separate entity.

**TREATMENT**
The conservative medical approach is usually used for the treatment of abomasal ulcers in cattle.

**Blood transfusions**
Blood transfusions and fluid therapy may be necessary for acute hemorrhagic ulceration. The most reliable indication for a blood transfusion is the clinical state of the animal. Weakness, tachycardia and dyspnea are indications for a blood transfusion. A hematocrit below 12% warrants a transfusion. In the case of severe blood loss, a dose of 20 mL/kg BW may be necessary.

**Coagulants**
Parenteral coagulants are used but are of doubtful value.

**Antacids**
The goal of antacid treatment is to create an environment that is favorable to ulcer healing. This can be done by decreasing acid secretion (oral or parenteral administration of histamine type-2 receptor antagonists [H2 antagonists] and proton pump inhibitors) or neutralizing secreted acid (oral administration of magnesium hydroxide and aluminum hydroxide). The elevation of the pH of the abomasal contents would abolish the proteolytic activity of pepsin and reduce the damaging effect of the acidity on the mucosa.

**Histamine type-2 receptor antagonists**
These compounds increase gastric pH through selective and competitive antagonism of histamine at the H2-receptor on the basolateral membrane of parietal cells, thereby reducing acid secretion. H2-receptor antagonists are characterized pharmacologically by their ability to inhibit gastric acid secretion and kinetically by their similarity in absorption, distribution and elimination. Cimetidine and ranitidine are synthetic H2 antagonists that inhibit basal as well as pentagastrin- and cholinergic-stimulated gastric acid secretion. Both have been used extensively to treat gastric ulcers in many species, including horses, dogs and humans. Oral and parenteral administration of cimetidine and ranitidine increases abomasal pH in sheep and cattle. High doses of cimetidine (20 mg/kg BW intravenously, or 50–100 mg/kg orally) increase abomasal pH in weaned lambs for more than 2 hours. Daily oral administration of cimetidine (10 mg/kg BW for 30 d) to veal calves may facilitate healing of abomasal ulcers. Because ranitidine is three to four times more potent than cimetidine, results of studies in ruminants suggest that oral administration of cimetidine (50–100 mg/kg) and ranitidine...
should be considered for surgical correction. Surgical correction of perforated abomasal ulcers in calves is possible and may be successful.

**PREVENTION**

Recommendations for the prevention of abomasal ulceration in cattle cannot be given because the etiology is so poorly understood.

**REFERENCES**

**ABOMASAL BLOAT (DISTENSION) IN LABMNS AND CALVES**

Abomasal bloat or severe distension occurs in lambs and calves fed milk replacer diets. Feeding systems that allow lambs to drink large quantities of milk replacer at infrequent intervals predispose them to abomasal bloat. This situation can occur under ad libitum feeding when the supply of milk replacer is kept at about 15°C (59°F) or higher, and particularly if it is not available for several hours. Lambs fed warm milk replacer to appetite twice daily appear to be very susceptible to abomasal bloat. Ad libitum feeding of cold milk replacers containing few or no insoluble ingredients, and adequately refrigerated, results in little or no bloating.

The pathogenesis of the abomasal tympany is thought to be associated with a sudden overfilling of the abomasum followed by the proliferation of gas-forming organisms, which release an excessive quantity of gas that cannot escape from the abomasum. The severe distension causes compression of the thoracic and abdominal viscera and blood vessels leading to them. This results in asphyxia and acute heart failure. Affected lambs and calves will become grossly distended within 1 hour after feeding and die in a few minutes after the distension of the abdomen is clinically obvious. At necropsy, the abomasum is grossly distended with gas, fluid and milk replacer, which is usually not clotted. The abomasal mucosa is hyperemic.

Abomasal bloat also occurs in Norway in lambs 15-30 days of age just prior to being turned on to pasture. Housing these lambs on floors with built-up litter when silage is used as a roughage is a predisposing environmental factor. It is postulated that affected lambs eat bedding contaminated with feces, which may result in the growth of an abnormal gas-producing microflora in the abomasum.

Abomasal bloat, hemorrhage and ulcers occur in young lambs in Norway. Affected lambs are 3-4 weeks of age. The major clinical findings are tympany and colic. There is severe abdominal pain, such as stretching of the hind legs, lifted tails, repeated attempts to defecate and anorexia. Untreated lambs die within a few hours but some lambs are found dead without having shown any clinical signs. Some lambs are anemic and have melena.

Affected lambs, approximately 1 week before developing abomasal bloat, had significantly lower serum iron levels than unaffected lambs. The administration of iron dextran to lambs during their first week of life reduced the incidence of abomasal bloat, suggesting that iron deficiency may be a predisposing factor.

At necropsy, there is abomasal tympany, abomasal hemorrhage and ulceration. Lambs with ulcers had a higher frequency of trichophytozaeobora than the cases without ulcers or the controls. Sarcina-like bacteria were found in sections of and smears from the abomasum in 79% of cases. Clostridium fallax and Clostridium sordelli were also cultured from some cases, but their causative significance is uncertain.

**REFERENCES**

**OMENTAL BURSITIS**

Inflammation of the omental bursa occurs rarely, usually in dairy cattle. The causes include perforated abomasal ulcers of the medial wall of the abomasum, penetration of the ventral wall of the blind sac of the rumen, penetration of the reticulum by a foreign body, spread of an umbilical infection to the greater omentum, extension of an abdominal abscess and localized peritonitis, with subsequent spread to the omental bursa secondary to postpartum metritis. Inflammation of the bursa results in the accumulation of inflammatory exudate in the bursal cavity, which enlarges beyond its normal capacity. There may also be rupture of the

leaves of the greater omentum, resulting in diffuse peritonitis, ileus or functional obstruction of the intestines. Clinical findings include anorexia of several days' duration, chronic toxemia, dehydration and abdominal distension, particularly of the right lower flank. Fluid-splashing sounds may be audible on auscultation and percussion of the right flank. On rectal examination a large, amorphous, spongy mass may be palpable anterior to the pelvic brim in the right upper quadrant of the abdomen. The peritoneal fluid may reveal evidence of a chronic suppurrative inflammation. A neutrophilia and an increase in the serum fibrinogen are common. There may also be a metabolic alkalosis with hypochloremia and hypokalemia. Treatment consists of surgical drainage and long-term therapy with antimicrobials. At necropsy there is diffuse fibrinous and necrotizing peritonitis and a large accumulation of purulent exudate in the omental bursa.

Diseases of the intestines of ruminants

CECAL DILATATION AND VOLVULUS IN CATTLE

Cecal dilatation occurs primarily in dairy cattle in the first few months of lactation. The cecum may be dilated with gas or distended with ingesta, and volvulus may occur. Clinically it is characterized by inappetence, drop in milk production, decreased amount of feces, a pin over the right upper flank and a distended, easily recognizable viscus on rectal palpation. The prognosis is usually good if the diagnosis is made early.

ETIOLOGY

The etiology is uncertain. Experimentally, a rise in the concentration of volatile fatty acids in the cecum can result in cecal atony. Dietary carbohydrates not completely fermented in the rumen are fermented in the cecum, resulting in an increase in the concentration of volatile fatty acids, a drop in pH and cecal atony. Butyric acid has the greatest depressant effect on cecal motility while acetate has the least. Inhibition of cecal motility may lead to accumulation of ingesta and gas in the organ and consequently dilatation, displacement and possible volvulus.

The concentrations of absolute and undissociated acetic, propionic, butyric, i-valerianic and n-valerianic acids, and total volatile fatty acids are significantly higher in samples collected from the cecum and proximal loop of the ascending colon of cows with cecal dilatation or dislocation compared with concentrations in control cows. However, the role of increased concentrations of volatile fatty acids in the etiology and pathogenesis of cecal dilatation or dislocation is uncertain.

EPIDEMIOLOGY

Dilatation and volvulus of the cecum occurs in well-fed, high-producing dairy cows 3-5 years of age during the first 12 weeks after parturition. The disease occurs throughout the year but most commonly during the calving season in North America and Europe. There is a record of five cases occurring in lactating dairy cows on one farm within 9 days. The cows were pastured day and night on grass dominated by white clover and received a 22% crude protein concentrate in the milk parlor twice daily in addition to silage. Cecal volvulus has also been described in sheep.

Atony or hypotonicity affecting the cecum and proximal loop of the ascending colon is thought to initiate the disease, leading to dilatation and displacement, including volvulus. The feeding of grain increases the concentration of volatile fatty acids in the cecum, lowering the pH of cecal contents and inhibiting cecal motility.

PATHOGENESIS

The pathogenesis of cecal dilatation, displacement and volvulus is thought to be similar to that which occurs in dilatation and displacement of the abomasum. The combination of intestinal gas and decreased cecal motility results in accumulation of fluid and gas in the cecum followed by dilatation and displacement of the cecum into the pelvic inlet. This results in a mild indigestion, or the dilatation may be subclinical and may be detected incidentally when the cow is examined for other purposes. There may be volvulus or torsion of the cecum but the outcome is probably the same.

In cecal volvulus, the apex of the cecum is rotated cranially and the cecal body becomes distended. The viscus and the first few segments of the proximal loop of the ascending colon twist about the mesentery, causing incarceration and eventually strangulation obstruction of the affected portions of the intestine. Torsion is a condition in which the cecum is twisted on its longitudinal axis; it may occur cranial to the ileoceccolic junction, at the ileoceccolic junction, or caudal to the junction. Torsion of the cecum may occur to the left or right and in each case involves the proximal loop of the ascending colon. The net effect is partial or total obstruction of the intestinal tract, accumulation of gas and/or ingesta in the cecum, varying degrees of paralytic ileus, reduced amount of feces and necrosis of the cecum because of ischemia. Cecal impaction is characterized by gross distension of the viscus with dry ingesta and in a mature cow the cecum may measure 90 cm in length by 20 cm in diameter.

The severity of the disease depends primarily on the degree of twisting of the cecum and its adjacent spiral colon, which results in ischemic necrosis. Rarely, a prolapse of the small intestine through a tear in the mesentery of the small intestine near its root may also pull the cecum cranially by the ileoceccolic fold and cause an anticlockwise volvulus as viewed from the right side of the animal.

It has been postulated that hypomotility of the cecum and proximal loop of the ascending colon may be responsible for the delayed recovery from and recurrence of cecal dilatation and displacement that occur following surgical evacuation of the cecum. However, the myoelectric activity of the cecum and proximal loop of the ascending colon in cows after spontaneous dilatation and displacement of the cecum indicates that delayed recovery is not caused by hypomotility. The myoelectric activity of the cecum is well coordinated with the ileum and the proximal loop of the ascending colon.

CLINICAL FINDINGS

In cecal dilatation without volvulus, there are varying degrees of anorexia, mild abdominal discomfort, a decline of milk production over a period of a few days and a decreased amount of feces. In some cases there are no clinical signs and the dilated cecum is found coincidentally on rectal examination. In simple dilatation, the temperature, heart rate and respirations are usually within normal ranges. A distinct ping is detectable on percussion and simultaneous auscultation in the right paralumbar fossa, extending forward to the 10th intercostal space. Simultaneous ballottement and auscultation of the right flank may elicit fluid-splashing sounds. There may be slight distension of the upper right flank but in some cases the contour of the flank is normal.

In cecal volvulus, anorexia, ruminal stasis, reduced amount or complete absence of feces, distension of the right flank, dehydration and tachycardia are evident, depending on the severity of the volvulus and the degree of ischemic necrosis. There may be some evidence of mild abdominal pain characterized by treading of the pelvic limbs and kicking at the abdomen. The ping is centered over the abdomen. The ping is centered over the abdomen. The ping is centered over the abdomen.
On rectal examination the distended cecum can usually be palpated as a long, cylindrical, movable organ measuring up to 20 cm in diameter and 90 cm in length. Palpation and identification of the blind end of the cecum directed towards the pelvic cavity is diagnostic. In simple dilatation, with minimal quantities of ingesta, the cecum is enlarged and easily compressible on rectal palpation. In cecal volvulus, the viscus is usually distended with ingesta and feels enlarged and tense on rectal palpation. The blind end of the cecum may be displaced cranially and laterally or medially, and the body of the cecum is then felt in the pelvic cavity. Varying degrees of distention of the colon can be visualized from the middle region of the colon can be visualized ultrasonographically. Dilatation and caudal displacement of the cecum and dilatation and craniodorsal retroflexion of the cecum can be visualized. In some cows, the direction of the retroflexed cecum cannot be determined.

CLINICAL PATHOLOGY
A mild degree of dehydration may be present and a compensated hypochloremia and hypokalemia occur. Hematological values are normal in most affected cattle unless there is necrosis of the cecum accompanied by peritonitis.

DIFFERENTIAL DIAGNOSIS
• Cecal dilatation and volvulus must be differentiated from right-side dilatation and volvulus of the abomasum. The ping in cecal dilatation and volvulus is usually centered in the paralumbar fossa; in abomasal dilatation and volvulus it is usually centered over the last few ribs and lower in the middle third of the right abdomen. The distended cecum is usually easily palpable rectally in the upper part of the abdomen and is readily identified as the cecum because it is movable. In dilatation and volvulus of the abomasum, the distended viscus is - usually palpable in the right lower quadrant of the abdomen much further forward than a dilated cecum and not movable. In many cases, the distended abomasum can barely be touched with the tips of the fingers, while the distended cecum can be palpated easily.
• Intestinal obstruction of the small intestines or other parts of the large intestine are characterized by subacute abdominal pain, absence of fces, more marked systemic signs such as dehydration and tachycardia, and perhaps the presence of distended loops of intestine on rectal examination can occur in 2-4 days. The use of parasympathomimetic drugs such as neostigmine given subcutaneously every hour for 2-3 days has been recommended but controlled trials were not done. Xylazine is contraindicated for the abdominal pain associated with cecal dilatation because it reduces myoelectrical activity of the cecum and proximal loop of the ascending colon. Ciapride at 0.08 mg/kg BW shows some promise. Bethanechol at 0.07 mg/kg BW and neostigmine at 0.02 mg/kg BW increased the frequency of cecocolic spike activity, the duration of cecocolic spike activity and the number of cecocolic propagated spike sequences every 10 minutes. Bethanechol is considered superior to neostigmine because it induces more pronounced coordinated and aborally propagated spike activity.

Surgical correction
For torsion and volvulus with the accumulation of ingesta and the possibility of necrosis of the cecum, the treatment of choice is surgical correction and the prognosis is usually good. The recurrence rate of cecal dilatation and displacement ranges from 11-13% within the first week after surgery, whereas the long-term recurrence rate is about 25%. In severe cases with necrosis of the cecum, partial resection or total typhlectomy may be necessary. Extensive cecal necrosis requires total typhlectomy, which can be successful and lactating dairy cows may thrive and their milk production may be excellent in the current lactation.

REFERENCES

INTESTINAL OBSTRUCTION IN CATTLE
Intestinal obstructions in cattle include volvulus, intussusception and strangulation. The characteristic clinical findings are anorexia, abdominal pain, absence of fces, the passage of dark fecal blood and mucus, dehydration and acid-base imbalance...
and death if physical obstructions are untreated.

**ETIOLOGY**

Physical obstruction of intestine due to intussusception, volvulus, strangulation, mesenteric torsion, luminal blockages

**Epidemiology**

Uncommon, but do occur

**Signs**

Abdominal pain (treading of hindlegs, stretching, kicking at abdomen), scant or absence of feces, faces may be bloodstained, rumen stasis, distension of abdomen (later stages), distended loops of intestine, progressive dehydration and toxemia leading to shock and recumbency

**Clinical pathology**

Hypochloremic, hypokalemic, metabolic alkalosis, hyperconcentration

**Lesions**

Intussusception, volvulus, strangulation, peritonitis

**Diagnostic confirmation**

Laparotomy

**Differential diagnosis**

Adult cattle: diffuse peritonitis, acute local peritonitis, abomasal ulcers, right-side displacement and volvulus of abomasum, grain overload, duodenal ileus, urethral obstruction in male ruminants. Calves under 2 months of age: abomasal dilatation – dietary in origin, abomasal volvulus, perforated abomasal ulcers, intussusception, torsion of root of mesentery, acute diffuse peritonitis, peracute to acute enteritis

**Treatment**

Surgical correction

**Control**

Nothing reliable

---

**ETIOLOGY AND EPIDEMIOLOGY**

The commonest causes are the intestinal accidents – volvulus, intussusception and strangulation – in which there is physical occlusion of the intestinal lumen. A functional obstruction occurs with local or general paralytic ileus – the lumen remains physically patent but there is no passage of ingesta along it. There are three common groups of causes:

- Physical obstruction of the intestinal lumen along with infarction of the affected section of intestine – intestinal accidents
- Physical obstruction of the intestinal lumen – luminal blockages
- Functional obstructions with no passage of intestinal contents but with the lumen still patent – paralytic ileus.

**Intestinal accidents**

Volvulus

Volvulus of the small intestine is rare and sporadic in cattle and occurs more commonly in dairy cattle than beef cattle. It is not more common in calves than in adults but there may be a decreased risk in cattle over 7 years of age compared to calves under 2 months of age.

Mesenteric torsion

This is the most common in calves and young cattle, e.g. coiled colon on its mesentery.

As in cecal torsion, the colon may be dilated before torsion develops. A case has been described in a mature cow, which recovered following surgery.

**Intussusception**

Intussusceptions are rare in cattle and most common in calves under 2 months of age. The high prevalence of diarrhea due to enteritis in calves suggests that enteritis may be a risk factor in this age group.

**Four types of intussusception** are recognized in cattle:

- The enteral type involves one segment of the small intestine, usually the distal jejunum or ileum, invaginating into another. The enteric type is most common in adults, with the distal jejunum most commonly affected due to the length and mobility of its mesenteric attachments. The high incidence of jejunojejunal intussusception in cattle has been attributed to the length and mobility of the jejunal mesenteric attachments, especially the distal third
- In the ileocecal type, the ileum invaginates into the cecum or into the proximal colon at the cecocolic junction
- The cecocolic type occurs with invagination of the cecal apex into the proximal colon
- In the colonic type, invagination of the proximal colon, or sometimes the spiral colon, occurs into a more distal segment.

The latter three do not occur commonly in adult cattle, presumably because the mesenteric fat deposits and the ileocecal ligament stabilize the intestine. In calves, the incidence of intussusception is more uniformly distributed among the four types, presumably because of the thin, fragile nature of the mesentery, which may be more susceptible to tearing under tension and allowing increased movement of adjacent segments of intestine. A series is recorded in cows with intestinal polyposis; polyps in the mucosa dragged a section of intestine into an invagination in the next section. There is also intussusception of colon into spiral colon; and intussusception of the spiral colon has been described in an adult bull. One recorded intussusception has been associated with a transmural adenocarcinoma in an aged cow.

**Strangulation**

Strangulation may occur through a mesenteric tear or behind a persistent vitelloumbilical band, the ventral ligation of the bladder, through the lateral ligation of a bull’s bladder, or via an adhesion, especially one between the omentum and an abscess of the umbilical artery in a young animal. Rupture of the small intestinal mesentery and strangulation of the intestine has been described in adult postparturient cows. A persistent urachus can also cause intestinal strangulation in mature cattle. Herniation of distal jejunum into a partially everted urinary bladder of a mature cow has been reported. Strangulation of the duodenum by the uterus during late pregnancy in cows has been described. The whole of the uterus had passed through a gap between the mesoduodenum and duodenum and with increasing weight had led to strangulation of the duodenum. The mesoduodenum and both walls of the greater omentum adjacent to its caudal edge were not connected with the duodenum, probably as a result of a congenital inhibitory malformation.

**Gut tie**

Has been described in male cattle that have recently been castrated using the open method and traction of the spermatic cord. When the spermatic cord is pulled and broken during castration, it may recoil through the inguinal ring and become entangled around small intestine, causing a physical obstruction. It is also possible that traction of the spermatic cord may tear the peritoneal fold of the ductus deferens that attaches the ductus to the abdominal wall, permitting loops of intestine to pass through this hiatus and resulting in incarceration.

**Compression stenosis**

This may arise from a blood clot from an expressed corpus luteum site on an ovary, or traumatic duodenitis caused by migration of a metallic foreign body.

**Cecal dilatation**

This can be followed by cecal volvulus (see Cecal dilatation and volvulus, above).

**Incarceration of small intestine**

Incarceration by remnants of the ductus deferens is recorded.

**Luminal blockages**

External pressure

External pressure by fat necrosis of mesenteries and omenta, and also lipomas may occur.

**Ileal impaction in cows**

Ileal impaction in Swiss Braunvieh cows in Switzerland has been described. The cause is uncertain but may be related to seasonal influences and winter feeding with a hay-based ration.

**Fiber-balls or phytobezoars**

These may be common in areas where fibrous feeds, e.g. *Romules bulbocodium* or tree loppings, form a large part of the diet. The ability of *R. bulbocodium* to survive dry
autumns and dominate the pasture insures that many fiber balls develop in the abomasum in autumn. Obstructions do not occur until the next spring when pasture is lush. The disease is common in late pregnancy or the first 2 weeks of lactation or after a period of activity such as estrus. Bezoars pass at this time from the abomasum into the first part of the duodenum, where they stick fast. 

**Trichobezoars (hairballs)**
In cold climates a more common obstruction is by trichobezoars. Cattle confined outside have long shaggy hair coats and licking themselves and others probably leads to ingestion of the hair. Hairballs causing obstruction of the small intestine of young beef calves has been described.13

'Rectal paralysis'
In cows near parturition, an apparent rectal paralysis leading to constipation may occur. The cause is unknown but is considered to be the result of pressure by the fetus or fetuses on pelvic nerves.

**Duodenal ileus**

- **Duodenal ileus caused by obstruction or compression of the duodenum has been described in mature cows.15** The lumen may be obstructed by phytobezoars, blood clots, or compression from or adhesion to a liver abscess.

**Functional obstructions**
Peritonitis and hypocalcemia are two common causes of functional obstruction in cattle.

### PATHOGENESIS

**Physical obstruction**

Physical obstruction of the small intestines of cattle results in an absence of feces, distension of the intestine cranial to the obstruction with fluid and gas, acute abdominal pain and a hypochloremic, hypokalemic metabolic alkalosis and dehydration. The alkalosis results from small-intestinal and abomasal reflux into the rumen, with chloride and hydrogen ion sequestration in the abomasum. Ileus of the small intestines is one of the most common consequences of obstruction, resulting in distension and hypomotility cranial to the obstruction. The myoelectric activity patterns occurring during small intestinal obstruction are disorganized in the segment orad to the obstruction, characterized by rapidly migrating, prolonged, high-amplitude spikes that sometimes occur in clusters.14 This probably accounts for the intermittent abdominal pain.

**Ileal impaction** in Swiss Braunvieh cows in Switzerland is characterized clinically by anorexia, sudden drop in milk production and some evidence of colic, including shifting of weight from leg to leg and occasional kicking at the abdomen. The ventral aspect of abdomen was enlarged and pear-shaped, and a tense abdominal wall was present in some cows. A ping could be elicited over the right abdomen in most cows. The feces in the rectum may be reduced in amount or there may be none. On rectal palpation, dilated loops of both small and large intestine are usually palpable. On laparotomy, the impaction was situated at the ileocolic valve, and the ileum proximal to ileocecal junction was impacted with ingesta for up to 15 cm in length. The color of the serosa of the ileum and distal part of the jejunum was normal.

**Volvulus and intussusception**

- **Volvulus of the small intestine** is a rotation of the entire small intestine, with or without the cecum and spiral colon, or of only the distal third of the jejunum and the proximal portion of the ileum about its mesenteric axis. The volvulus results in intestinal distension, vascular compromise, intestinal necrosis and eventual death unless surgically corrected.

**Intussusception** is the invagination of one portion of the intestine into the lumen of an adjacent segment of intestine. Jejunojejunal intussusception is the most common form in cattle, although isolated cases of ileocecal, ileoceccolic, cecocolic and colocolic intussusception also occur. In most cases the intussusception is single, but doubles do occur. There are reports of cattle surviving after sloughing of an intussusception but these are rare and death usually occurs 5–8 days after the onset of clinical findings if surgical correction is not carried out.

In general, the effects of intestinal accidents in cattle are not as remarkable as in the horse. Neither the abdominal pain nor the cardiovascular collapse is as severe in adult cattle as in horses with similar lesions. The exception is in calves, in which the effects are more marked and more rapid. Distension of the abdomen occurs much more frequently in calves than in adult cattle. Involvement of large segments of intestine as in torsion of the root of the mesentery may result in metabolic acidosis because of the rapid onset of shock. Ischemic necrosis of the intestinal wall results in various degrees of severity of peritonitis and abnormal peritoneal fluid containing erythrocytes, leukocytes and increased serum proteins.

Hemorrhage into the intestinal tract at the level of the obstruction results in the passage of small quantities of dark blood, which may be almost black if the obstruction is high up in the small intestinal tract. Distension of intestines with fluid and gas cranial to the obstruction may cause some mild distension of the abdomen but primarily if the large intestine is obstructed as in torsion of the coiled colon. The longer duration of the disease and the profound depression that develops suggest that endotoxemia, as in horses, may be the lethal agent, but the course is much slower than in the horse.

The effect of myoelectric activity of the cecum and proximal loop of the ascending colon on motility of this segment of intestine in experimental obstruction of the large intestine in cattle has been examined.14 Obstruction of the colon results in prestenotic hypermotility (colic motor complex) or prolonged propulsive peristaltic waves directed toward the obstruction site. This may represent an effort of the intestine to overcome the obstruction in order to re-establish the continuity of the passage of ingesta.

Patterns of myoelectric activity in the small and large intestine of cows orad and aborad to an obstruction site have been measured.15 Myoelectric activity in the ileum immediately orad to the occlusion was characterized by abolition of the migrating myoelectric complex and a constant pattern of strong bursts of long duration. Organized cyclic activity occurred in the large intestine despite complete disruption of the small-intestinal migrating myoelectric complexes, indicating the presence of mechanisms able to initiate and regulate coordinated myoelectric patterns in the large intestine independently of the small intestine.16

**Duodenal ileus**

In duodenal ileus caused by obstruction of the lumen by phytobezoars or compression of the duodenum by a liver abscess associated with traumatic reticulo-peritonitis in mature cows, there is abomasal and duodenal reflux into the rumen resulting in metabolic alkalosis with hypochloremia and increased ruminal chloride.13 The obstruction caused by phytobezoars and liver abscesses may occur at almost any segment of the duodenum.13 The ileus results in a marked reduction in gastrointestinal motility and distension of the fore- stomach and abomasum due to the accumulation of excessive quantities of fluid, which results in dehydration. Abdominal pain is associated with the distension of the duodenum. The ileus results in marked decrease in movement of ingesta and the feces are markedly reduced in quantity. Duodenal obstruction caused by malposition of the gall-bladder in a heifer has been described.17

**Functional obstruction**

In functional obstruction, there is paralytic ileus and an increase in the transit time of ingesta and feces. The feces are scant and do not contain blood.
Sequestration of fluids in the intestines may result in varying degrees of dehydration and a metabolic alkalosis with hypochloremia and hypokalemia.

**CLINICAL FINDINGS**

**General findings**

There is an initial attack of acute abdominal pain in which the animal kicks at its abdomen, treads uneasily with the hindlegs, depresses the back and may groan or bellow from pain. The pain occurs spasmodically and at short, regular intervals and may occasionally be accompanied by rolling. This stage of acute pain usually passes off within a few (8–12) hours and during this time there is anorexia and little or no feces are passed. The temperature and respiratory rates are relatively unaffected and the heart rate may be normal or elevated, depending on whether or not blood vessels are occluded. If there is infarction of a section of intestine there will be signs of endotoxic shock, including low blood pressure, very rapid heart rate, and muscle weakness and recumbency. These signs are absent in cases where the blood supply of the intestine is not compromised. For example, in cecal torsion the heart rate may be normal. In all cases, as the disease progresses and dehydration becomes serious the heart rate rises and may reach as high as 100/min just before death.

When the acute pain has subsided, the cow remains depressed, does not eat nor ruminate and passes no feces. The circulation, temperature and respirations are usually within normal limits and ruminal activity varies. In most cases there is complete ruminal stasis but, in exceptional cases, movements will continue, though they are usually greatly reduced. The rumen pack feels dry and firm on palpation through the abdominal wall.

**Abdomen**

The abdomen is slightly distended in all cases. Where there is distension of loops of intestine, as in ileus due to dietary error, there may be some distension of the right abdomen. Fluid-splashing sounds can be elicited by ballottement and simultaneous auscultation over the right abdomen in most cases and in a minority of cases over the left abdomen. With obstruction of the pylorus the splashing sounds can be elicited only on the right side, just behind the costal arch and approximately halfway down its length. Regurgitation of fluid ingesta through the nose is common.

**Feces**

The character of the feces is highly variable. In the early stages they will be normal but passed frequently and in small amounts. It may be necessary to carry out a rectal examination because the feces may not be passed from the anus. In some cases they will be hard, turd-like lumps, usually covered with mucus. Blood is often present, not as melena but as altered red blood, in the form of a thick red slurry, leaving dried flakes of it around the anus, especially in intussusception. The last fecal material is more mucoid and may consist entirely of a plug of mucus. In some cases of obstruction caused by fiber balls the fecal material is pasty, evil-smelling and yellow-gray in color.

**Rectal examination**

When there is intussusception or volvulus of the small intestine, the affected segment is usually felt in the lower right abdomen but the site varies with the nature of the obstruction. It is important to appreciate that not all intestinal obstructions can be palpated on rectal examination. It depends on the location of the affected segment of intestine: those in the anterior part of the abdomen are not palpable, those in the caudal part of the abdomen may be palpable. In addition, the affected segment may or may not be palpable, and the adjacent segments cranial to the obstruction may be palpable as distended segments of intestine.

In intussusception the affected segment may be palpable, usually as an oblong, sausage-shaped mass of firm consistency, but if a long length of intestine is involved a spiral develops and is palpable as such. In volvulus the intestinal loop may be small, soft and mobile. In many cases, it is possible to follow tightly stretched mesenteric bands coursing dorsally in the middle part of the abdomen. Palpation of distended loops of intestine may cause distress, especially in the early stages, and tension of a number of loops may increase intra-abdominal pressure to the point where entry of the hand beyond the pelvis is difficult. Within a few days, the rectum is empty except for tarry mucus and exudate and insertion of the arm usually causes pain and vigorous straining. Distension of loops of intestine is not nearly as obvious as in horses with intestinal obstruction and may not occur unless the colon or cecum is involved.

**Duodenal ileus**

*Duodenal ileus* in mature cows is characterized by anorexia, depression, dehydration, abdominal pain (treading, kicking and stretching, frequent lying down and standing up), rumen distension and hypotonicity, moderate bloating in some cases, scant feces and the presence of fluid-splashing sounds on auscultation and ballottement of the right abdomen. Rectal examination may reveal no abnormal findings or an enlarged L-shaped rumen and distended loops of small intestine. Ultrasonography can be used to visualize the distended duodenum in the 10th to 12th intercostal spaces. If only one loop of intestine is visible, it indicates distension of the duodenum; when several loops of intestine are visible it indicates ileus of the jejenum or ileum. Duodenal obstruction caused by malposition of the gallbladder in cattle can be diagnosed using abdominal ultrasonography and laparotomy.

Torsion of the coiled colon (mesenteric root torsion)

This can cause death in less than 24 hours. It is characterized by distension of the right abdomen and a number of distended loops of intestine can be palpated. When there is torsion or dilatation of the cecum, there is usually one grossly distended intestinal loop extending horizontally across the abdomen just cranial to the pelvis and caudally or medially to the rumen. It may be possible to palpate the blind end of the cecum, and in cases which have been affected for several days the organ may be so distended with fluid and gas that it can be seen through the right flank, or fluid sounds can be produced by ballottement or simultaneous percussion and auscultation. Rarely, the distended cecum may be located in the left paralumbar fossa between the rumen and the abdominal wall, in a position reminiscent of an LDA. The disease is likely to recur in the same cow in subsequent years, and a case of chronic dilatation that persisted for 10 months is recorded.

**Lipomas and fat necrosis**

These abnormalities are usually easily palpable as firm, lobulated masses that can be moved manually. They may encircle the rectum. An obstructing phytobezoar may be palpable on rectal examination in the right anterior abdomen. It is usually 5–15 cm in diameter and so mobile that when touched it may immediately pass out of reach. Affected cattle may remain in this state for 6–8 days but during this time there is a gradual development of a moderate, pendulous, abdominal enlargement, profound toxemia and an increase in heart rate. The animal becomes recumbent and dies at the end of 3–8 days.

**CLINICAL PATHOLOGY**

Clinicopathologic findings are generally nonspecific and of limited assistance in making a diagnosis or assessing prognosis preoperatively.
Serum biochemistry
Hypochloremia, hypernatremia, azotemia, and hyperglycemia are common.3

Differential Diagnosis
- Acute intestinal obstruction in mature cattle is characterized by sudden onset of anorexia, reticulorumatous pain, moderate abdominal pain, scant feces, fluid-splashing sounds over the right abdomen, possibly distended loops of intestine on rectal palpation, and a progressively worsening course. It must be differentiated from other diseases of the forestomach and abomasum that result in scant feces, reduced reticulorumatous activity, abdominal pain, and distended loops of intestine on rectal examination (see Table 6.2). Those diseases include: vagus incoordination with or without abomasal impaction, diffuse peritonitis, RDW, abomasal ulcers, duodenal ulcers (see Table 6.2)
- Hemorrhagic jejunitis syndrome of dairy cattle is a sporadic disease characterized by sudden anorexia and loss of milk production, moderate abdominal distension, weakness leading to recumbency, bloody to dark feces (melena), fluid-splashing sounds on ballottement over the right abdomen, tachycardia and distended firm loops of small intestine palpable on rectal examination. The case fatality rate is high. At necropsy there is severe necrohemorrhagic enteritis or jejunitis with intraluminal hemorrhage or blood clots.
- Cecal dilatation and volvulus is characterized by gastrointestinal stasis with inaptness, possibly distension of the right abdomen, a high-pitched pitch on auscultation and percussion of the right paralumbar fossa, and the cecum is easily identifiable by rectal examination
- Renal and ureteric colic may simulate intestinal obstruction but occur rarely. Acute involvement of individual renal papillae in pyelonephritis in cattle is also thought to cause some of these attacks of colic.
- Urethral obstruction in male ruminants causes abdominal pain but there are additional signs of grunting, straining, distention of the urinary bladder and tenderness of the urethra. Defecation is not affected.
- Photosensitive dermatitis in cattle is also accompanied by kicking at the belly but the skin lesions are obvious and there are no other alimentary tract signs
- Acute intestinal obstruction in calves under 2 months of age must be differentiated from abomasal dilatation – dietary in origin, abomasal volvulus, perforated abomasal ulcers, intussusception, torsion of the root of mesentry, acute diffuse peritonitis, peracute to acute enteritis and gastrointestinal tympy – dietary in origin. The salient features of each of these diseases is summarized in Table 6.4

Nonsteroidal anti-inflammatory drugs
NSAIDs have also been used for their anti-inflammatory and antiendotoxin effects.

REFERENCES

Hemorrhagic bowel syndrome in cattle (jejunal hemorrhage syndrome)
Hemorrhagic bowel syndrome, also known as jejunal hemorrhage syndrome of cattle, is a recently recognized disease of cattle characterized clinically by a syndrome similar to obstruction of the small intestine causing abdominal distension, dehydration and shock due to necrohemorrhagic enteritis affecting primarily the small intestine. At necropsy there is segmental necrohemorrhagic enteritis of the small intestine and large intraluminal blood clots. In spite of intensive medical and surgical therapy, the prognosis is unsatisfactory and the case fatality rate is almost 100%

Etiology
The etiology is unknown. C. perfringens type A has been isolated from the intestines of naturally occurring cases but its significance is uncertain. Because C. perfringens type A can be found in the intestinal tracts of healthy cattle and is able to proliferate quickly after death, the role of the organism in the pathogenesis of hemorrhagic jejunitis is uncertain

Epidemiology
The disease occurs sporadically, primarily in mature lactating dairy cows in North America.12 Individual cases have occurred in beef cows.3 In Germany, the disease occurs in Simmental cattle.4

The morbidity is low but the case fatality rate is almost 100%.3
Investigations of herds with cases have failed to identify any reliable possible risk factors. Most cases occur in lactating dairy cows in the first 3 months of lactation. In a single dairy herd, 22 cases occurred in a period of 4 years. Affected cows ranged from 2–8 years of age and the time since parturition ranged from 9–319 days.

A mail and conference survey of dairy cattle veterinarians in Minnesota found that the disease occurred with greatest frequency in lactating dairy cows in early lactation under a wide variety of management systems, in varying herd sizes and in both free-stall and tie-stall housing systems. The incidence appeared to be higher in herds of more than 100 cows and in herds using total mixed rations.

As part of the National Animal Health Monitoring System's Dairy 2002, information was collected about hemorrhagic jejunitis in dairy cattle in the USA. The disease was observed in 9.1% of herds within the previous 5 years and in 5.1% of herds during the preceding 12 months. Risk factors found to be associated with the disease during the preceding 12 months were large herd size, administration of bovine somatotrophin and routine use of milk urea nitrogen concentration to determine ration composition. Use of pasture as part of the lactating cow ration during the growing season was associated with decreased odds of the disease in herds with a rolling herd average milk production of 20,000 lb or less, whereas in herds with higher milk production, use of pasture was not associated with the occurrence of the disease. For individual cows with signs consistent with the disease, the third lactation was associated with the occurrence of the disease. Administration was collected about hemorrhagic jejunitis in dairy cattle in the USA.

The primary lesion is an acute localized necrotizing hemorrhagic enteritis of the small intestine leading to the development of an intraluminal blood clot, which causes a physical obstruction of the intestine, and ischemia and devitalization of the wall of the affected segment of the intestine. The lesion is similar to hemorrhagic enterotoxemia associated with C. perfringens in young rapidly growing calves, lambs or piglets.

There is gastrointestinal stasis with accumulation of intestinal gas and fluids proximal to the obstructed intestine, resulting in distended loops of intestine, hypochloremia, hypokalemia, dehydration and varying degrees of anemia. The serum biochemistry changes are those of an obstruction of the upper small intestine and sequestration of abomasal secretions, with resultant hypokalemia and hypochloremia. The hemorrhagic enteritis is progressive, with the ischemia and necrosis extending through the intestinal wall, and within 24–48 hours there is marked fibrinous peritonitis, dehydration, continued electrolyte imbalance, marked toxemia and death.

**Clinical Findings**

Common historical findings include sudden anorexia and depression, marked reduction in milk production, abdominal distension, weakness progressing to recumbency, bloody to dark-red feces or dry scant feces, dehydration and abdominal pain, including bruxism, vocalization, treading and kicking at the abdomen. Sudden death without prior clinical findings has been reported.

On clinical examination there is depression, dehydration, the body temperature may be normal to slightly elevated, the heart rate is increased to 90–120 beats/min, the mucous membranes are pale and the respiratory rate is increased. The abdomen is usually distended moderately over the right side. The rumen is usually atonic. Fluid-splashing sounds are commonly audible by succession over the right abdomen. In some cases, a ping can be elicited over the right abdomen.

On rectal examination, the feces are black–red, jelly-like and sticky, and smell like digested blood. On deep palpation of the right abdomen, distended loops of intestine may be palpable, some of which are firm (those loops containing the blood clot) while others may be resilient, representing loops of intestine proximal to the blood clot obstruction that contain excessive fluid and gas and in which the intestine is in a state of ileus.

The course of the disease in most cases is 2–4 days. Even with intensive fluid and electrolyte therapy, affected animals continue to worsen progressively, become weak, recumbent and die, or euthanasia is chosen.

On laparotomy, the abomasum is commonly distended with fluid. Up to 60–100 cm of small intestine may be distended and firm to touch, with a markedly dark red to purplish hemorrhagic serosal surface covered with fibrin tags. The mesenteric band may be too tense to allow exteriorization of the affected intestine. Manipulation of the affected intestine may lead to its rupture because of its thin and fragile intestinal wall due to ischemia and devitalization. The small intestine proximal to the affected segment is usually distended with fluid and gas and compressible; that distal to the affected segment is usually relatively empty.

**Clinical Pathology**

**Hematology**

The hemogram is variable and not diagnostic. Leukocytosis and mature neutrophilia with increased band neutrophils and increased fibrinogen concentrations are common but neutropenia with a left shift may also occur. The PCV and plasma protein concentrations are variable.

**Serum Biochemistry**

Metabolic alkalosis with compensatory respiratory acidosis, hypokalemia and hypochloremia are common, which is consistent with abomasal outflow obstruction due to the obstruction caused by the clotted blood or ileus.

**Necropsy Findings**

The abdomen is moderately distended as a result of marked dilatation of the small intestine, which is dark red, hemorrhagic and commonly covered by fibrinous exudate. The affected segment of intestine, especially the jejunum and ileum, may be 1 m or more in length and contains a firm blood clot, adherent to the mucosa, which is necrotic and hemorrhagic over the entire length of the affected portion.

Histologically, there is multifocal submucosal edema and neutrophil infiltration, segmental necrosis, ulceration, and mucosal and transmural hemorrhage (hematoma) of the jejunum. Frequently, the epithelium is completely sloughed and, in the area of attachment of the blood clot, the mucosa is absent. Extensive fibrin and neutrophil infiltration occur on the serosal surface and fibrinous peritonitis is common.

C. perfringens type A has been isolated from the intestinal contents of typical cases but its significance is unknown.

**Treatment**

No specific treatment is available. For valuable animals, intensive fluid and electrolyte therapy is indicated. Because of the possibility of clostridial infection, penicillin is indicated if treatment is attempted. Laparotomy and resection of the affected segment of the intestine and anastomosis is indicated but has been unsuccessful to date.
DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other causes of acute physical or functional obstruction of the small intestine causing distended loops of intestine, fluid-splashing sounds on ballottement of the abdomen and dehydration and electrolyte imbalances. These include intussusception, cecal dilatation and volvulus and diffuse peritonitis (causing ileus). In ileal impaction in mature cows, distended loops of intestine are palpable on rectal examination but on laparotomy the abnormalities consist of ileal impaction and distended loops of intestine which are amenable to treatment.

Diseases causing melena and dysentery include bleeding abomasal ulcers, acute salmonellosis and coccidiosis. Transabdominal ultrasonography (Fig. 6.8) can be used to detect ileus of the small intestine and distension of loops of small intestine with homogeneous echogenic intraluminal material compatible with intraluminal hemorrhage and clot formation.²

CONTROL

No control or prevention strategies have been developed.

REFERENCES

INTESTINAL OBSTRUCTION IN SHEEP

Intestinal obstructions are not commonly observed in sheep unless a series of them causes a noticeable mortality. Some notable occurrences have been:

- Heavy infestation with nodular worm (Oesophagostomum columbianum) leading to high prevalence of intussusception occlusion by adhesion
- High incidence of intussusception in traveling sheep for no apparent reason
- Cecal torsion (red-gut) in sheep grazing lush pastures of alfalfa or clover in New Zealand. Affected lambs survive only a few hours and up to 20% of a flock are affected. The outstanding postmortem lesion is a distended, reddened cecum and/or colon that has undergone torsion. The rumen is smaller and the large intestine larger than normal because of the high digestibility of the diet. All ages, except suckling lambs, are affected and the mortality rate may be as high as 20%. Sheep that are seen alive have a distended abdomen, show abdominal pain and have tinkling sounds on auscultation of the right flank.

TERMINAL ILEITIS OF LAMBS

This disease causes poor growth in lambs 4–6 months old. The circumstances usually suggest parasitism or coccidiosis. The terminal 50–75 cm of the ileum is thickened and resembles the classical lesion of Johne's disease. Chronic inflammation is evident and there are some shallow ulcers in the epithelium. The terminal mesenteric lymph node is enlarged. Histopathological examination of affected ileal wall shows mucosa thickened by epithelial hyperplasia, leukocytic infiltration and connective tissue infiltration. The cause is unknown, and the course of the disease has not been identified because most affected lambs are likely to be culled for ill-thrift.

Principles of hepatic dysfunction

DIFFUSE AND FOCAL HEPATIC DISEASE

The liver has a large reserve of function and approximately three-quarters of its parenchyma must be rendered inactive before clinical signs of hepatic dysfunction appear. Diffuse diseases of the liver are more commonly accompanied by signs of insufficiency than are focal diseases, which produce their effects either by the toxins formed in the lesions or by pressure on other organs, including the biliary system. The origin of a toxemia is often difficult to localize to the liver because of the physical difficulty of examining the organ.

Diffuse diseases of the liver can be classified as hepatitis and hepatosis according to the pathological change that occurs, and the classification also corresponds roughly with the type of causative agent. Clinically the differences between these two diseases are not marked, although some assistance can be obtained from clinicopathological examination.

HEPATIC DYSFUNCTION

There are no specific modes of hepatic dysfunction. The liver has several important functions and any diffuse disease of the organ interferes with most or all of the functions to the same degree. Variations occur in the acuteness and severity of the damage but the effects are the same and the clinical manifestations vary in degree only. The major hepatic functions that, when disordered, are responsible for clinical signs include:

- The maintenance of normal blood glucose levels by providing the source as glycogen
- The formation of some of the plasma proteins
- The formation and excretion of bile salts and the excretion of bile pigments
- The formation of prothrombin
- The detoxification and excretion of many toxic substances, including photodynamic agents.

The clinical signs produced by interference with each of these functions are dealt with under manifestations of hepatic dysfunction. A rather special aspect is the role of the liver in the genesis of primary ketosis of cattle.

PORTAL CIRCULATION

The portal circulation and the liver are mutually interdependent, the liver depending upon the portal vein for its supply of nutrients and the portal flow depending upon the patency of the hepatic sinusoids. The portal flow is unusual in that blood from the gastro-splenic area and the lower part of the large intestine passes to the left half of the liver and the blood from the two intestines to the right half, without mixing of the two streams in the portal vein. The restriction of toxicpathic hepatitis to one
half of the liver and the localization of metastatic abscesses and neoplasms in specific lobes results from the failure of portal vein blood from different gut segments to mix. The localization of toxipathic hepatitis may be because of selective distribution of the toxin or of protective metabolites. The passage of blood from the portal circuit through the liver to the caudal vena cava is dependent upon the patency of the hepatic vascular bed, and obstruction results in damming back of blood in the portal system, portal hypertension, interference with digestion and absorption, and in the final stages the development of ascites.

Manifestations of liver and biliary disease

JAUNDICE

Jaundice is a clinical sign that often arises in diseases of the liver and biliary system but also in diseases in which there are no lesions of these organs. It does not always occur and may be conspicuously absent in acute hepatitis. Although jaundice is a result of the accumulation of bilirubin, the staining is much more pronounced with conjugated (direct) bilirubin than with unconjugated (indirect) bilirubin. Thus the jaundice is more intense in cases of obstructive and hepatocellular jaundice than in hemolytic jaundice. The levels of bilirubin in blood also affect the intensity of the jaundice, the obstructive form often being associated with levels of bilirubin that are ten times higher than those commonly seen in hemolytic anemia. The staining of jaundice is due to staining of tissues, especially elastic tissue, and not to accumulation in tissue fluids, so that it is best detected clinically in the sclera, and jaundice that may be detectable easily at necropsy may not be visible on clinical examination. Many classifications have been suggested but the simplest is that proposed by Popper and Schaffner, illustrated in Figure 7.1.

The primary differentiation has to be made between jaundice with and without impairment of bile flow. Some indication of the type of jaundice can be derived from clinical examination. Thus jaundice is usually much more severe when impairment of flow occurs and when bile pigments are absent from the feces. However, obstructive jaundice can occur with only partial occlusion of hepatic flow provided at least half the bile flow is obstructed. In such cases jaundice may occur even though bile pigments are still present in the feces. With lesser obstruction the portion of the liver and biliary tract that is functioning normally excretes the extra load of bile pigments. The only accurate basis for the differentiation between jaundice with impaired bile flow and jaundice without impaired flow is the examination of the urine for the presence of bilirubin and urobilinogen and the determination of the relative amounts of conjugated and unconjugated bilirubin present in the serum. Unconjugated (indirect) bilirubin that has not passed through hepatic cells is not excreted by the kidney, so that in hemolytic jaundice the indirect bilirubin content of serum is increased markedly and, although the urine contains an increased amount of urobilinogen, no bilirubin is present. In those cases in which jaundice is caused by impairment of bile flow there is a marked increase in the serum level of conjugated (direct) bilirubin, and the bilirubin content of the urine is greatly increased. The amount of urobilinogen varies depending on whether any bilirubin reaches the intestine to be metabolized to urobilinogen and reabsorbed. In complete extrahepatic biliary obstruction urobilinogen is not present in the urine.

OVERPRODUCTION OR HEMOLYTIC JAUNDICE

Hemolytic jaundice is common in animals and may be associated with bacterial toxins, invasion of erythrocytes by protozoa or viruses, inorganic and organic poisons and immunological reactions. Diseases in which bacterial toxins cause intravascular hemolysis are bacillary hemoglobinuria of cattle and leptospirosis, although the mechanism by which hemolysis is produced in the latter disease does not seem to have been accurately determined. The common protozoan and viral diseases in which hemolysis occurs include babesiosis, anaplasmosis, eperythrozoonosis and equine infectious anemia. Chronic copper poisoning, selenium poisoning in sheep, phenothiazine poisoning in horses, pasturing on rape and other cruciferous plants and bites by some snakes are other common causes. Postparturient hemoglobinuria has an uncertain etiology but is usually attributed to a deficiency of
Manifestations of liver and biliary disease

**Hemolytic anemia** is one of the primary effects of severe, acute liver damage. A precipitate fall in blood glucose is accompanied by nervous signs, including hyperexcitability, convulsions and terminal coma. If the hepatic damage occurs more slowly the hypoglycemia is less marked and less precipitous and is accompanied by: inability to perform work, drowsiness, yawning and lethargy. With persistent hypoglycemia, structural changes may occur in the brain (hypoglycemic encephalopathy) and these may be the basis for the chronically drowsy animals or dummies.

However, hypoglycemia does not always occur in acute hepatitis and cannot be considered to be the only or even the most important factor in producing the cerebral signs.

**High blood levels of ammonia** occur in pyrrolidizine poisoning in sheep and calves by the intravenous infusion of ammonia. This role of ammonia as a cerebrotoxicant can be important in hepatopathies in which the detoxication function of the liver is lost, and also in congenital defects of hepatic vasculature in which blood is bypassed around the liver. In the latter case ammonia and similar toxic byproducts of protein degradation in the large intestine avoid the detoxication filter of the liver. Blood ammonia levels are increased and sulfobromophthalein sodium (BSP) dye clearance is delayed.

The most common cause of hyperammonemia and encephalopathy in the horse is a depression of hepatic function due to acute or chronic liver disease. The severity of encephalopathy clinically correlates well with the degree of hepatic functional compromise but only poorly with the degree of hyperammonemia. Other factors, such as hypokalemia, alkalosis, short-chain volatile fatty acids, and false and true neurotransmitters, may be important in the pathogenesis of hepatic coma in cattle and horses.

**Neurological disease** was reported in a 13-year-old horse with hyperammonemia and no gross or histological evidence of disease. The ammonia level was 475 μmol/L (normal 7–60 μmol/L). Neurological signs included apparent blindness, ataxia, falling, dysphagia, bruxism, circling, head pressing, muscle fasciculations, yawning and depression. Plasma ammonia levels are also significantly elevated in cattle with...
hepatic disease. Clinical signs of hepatic encephalopathy such as blindness, head pressing, excitability, ataxia and weakness, together with fever and jaundice, are grave prognostic signs. An intrahepatic porto-systemic shunt causing hepatoencephalopathy has been reported in a 3-month-old goat.

**EDEMA AND EMACIATION**

Failure of the liver to anabolize amino acids and protein during hepatic insufficiency is manifest by tissue wasting and a fall in plasma protein. This may be sufficiently severe to cause edema because of the lowered osmotic pressure of the plasma. Hepatic edema is not usually very marked and is manifested most commonly in the intermandibular space (bottle jaw). If there is obstruction to the portal circulation, as may occur in hepatic fibrosis, the edema is much more severe but is largely limited to the abdominal cavity.

**DIARRHEA AND CONSTIPATION**

In hepatitis, hepatic fibrosis and obstruction or stasis of the biliary system, the partial or complete absence of bile salts from the alimentary tract deprivets it of the laxative and mildly disinfectant qualities of these salts. This, together with the reflex effects from the distended liver in acute hepatitis, produces an alimentary tract syndrome comprising anorexia, vomiting in some species and constipation punctuated by attacks of diarrhea. The feces are pale in color and, if there is an appreciable amount of fat in the diet, there is steatorrhea.

**PHOTOSENSITIZATION**

Most photosensitizing substances, including phylloerythrin, the normal breakdown product of chlorophyll in the alimentary tract, are excreted in the bile. In hepatic or biliary insufficiency excretion of these substances is retarded and photosensitization occurs.

**HEMORRHAGIC DIATHESIS**

In severe diffuse diseases of the liver there is a deficiency in prothrombin formation and a consequent prolongation of the clotting time of the blood. Abnormality of the prothrombin complex is not the only defect, deficiencies of fibrinogen and thromboplast also occurring. Prothrombin and other factors in the prothrombin complex depend upon the presence of vitamin K for their formation and an absence of bile salts from the intestine retards the absorption of this fat-soluble vitamin. Parenteral administration of vitamin K is advisable before surgery is undertaken in patients with severe hepatic dysfunction.

**ABDOMINAL PAIN**

Two mechanisms cause the pain in diseases of the liver: distension of the organ with increased tension of the capsule, and lesions of the capsule. Acute swelling of the liver occurs as a result of engorgement with blood in congestive heart failure and in acute inflammation. Inflammatory and neoplastic lesions of the capsule, or of the liver parenchyma just beneath the capsule, cause local irritation to its pain end organs. The pain is usually subacute, causing abnormal posture, particularly arcing the back, and disinclination to move. Tenseness of the abdominal wall and pain on deep palpation over the liver area may also be detected in the majority of cases.

**ALTERATION IN SIZE OF THE LIVER**

Great variation in the size of the liver is often seen at necropsy but clinical detection is not easy unless the liver is grossly enlarged. This is most likely to occur in advanced congestion of the liver due to congestive heart failure, in some plant poisonings in horses and when multiple abscesses or neoplastic metastases occur. In acute hepatitis the swelling is not sufficiently large to be detected clinically and in terminal fibrosis the liver is much smaller than normal.

Atrophy of the right lobe of the liver occurs in the horse and may be related to chronic distension of adjacent segments of the intestinal tract. The normal equine liver is anatomically bisected into two approximately equal halves by the umbilical interlobar fissure; and additional interlobular fissures divide the liver into four distinct lobes in the foal: right, left, quadrate and caudate. In horses with right lobe atrophy, the capsule of the right lobe is wrinkled and thick when atrophy is severe. In clinically normal horses, the right lobe constitutes half of the total liver weight while the right lobe in horses with atrophy ranges from 11.0–38.8% of the total liver weight. This is thought to be due to long-term, insidious compression of this portion of the liver by abnormal distension of the right dorsal colon and base of the cecum.

**DISPLACEMENT OF THE LIVER**

The liver may be displaced from its normal position and protrude into the thoracic cavity through a diaphragmatic hernia, causing respiratory distress and abnormal findings on percussion of the chest. Torsion of a lobe of the liver has been recorded in aged sows in the early part of lactation. Inappetence, uneasiness and unwillingness to suckle the young were followed by severe, prolonged vomiting, acute abdominal pain and dyspnea. The twisted lobe was greatly increased in size and in one case the capsule was ruptured, leading to severe internal hemorrhage.

**RUPTURE OF THE LIVER**

Rupture of the liver is an occasional accident in animals, occurring usually as a result of trauma. In most instances rupture results in death from hemorrhage, although small breaks in the capsule may heal. Horses used for the production of serum frequently develop hepatic amyloidosis, presumably as a reaction to repeated injection of foreign protein, and the death rate from rupture of the liver is relatively high in this group. Amyloidosis is essentially a space-occupying lesion, which results in a liver with a friable texture. The amyloid masses exert pressure on liver cell cords and sinusoids, gradually causing pressure atrophy, ischemic degeneration and necrosis of hepatic parenchyma.

A high prevalence of liver rupture is recorded in newborn lambs of the North Country Cheviot breed. Losses resulting from the condition were 12.5% of all neonatal deaths in purebred lambs, and varied from 6.4–24.7% on individual farms. The lambs are stillborn, or are born alive but become anemic and weak and die within 12 hours of birth from internal hemorrhage. It is thought that the cause of the fatal anemia is an inherited short sternal, which exposes the liver to compression and rupture of its capsule. Vitamin E deficiency in the ewes and lambs may also be a factor.

**BLACK LIVERS OF SHEEP**

Dark brown to black pigmentation of the liver and kidneys occurs commonly in sheep in certain parts of Australia. No illness is associated with the condition but the livers are not used for human consumption for esthetic reasons and extensive financial loss may result. Commonly referred to as ‘melanosis’, the pigmentation has been determined to be the result of deposition of the pigment lipofuscin at various stages of oxidation. Areas in which the disease occurs carry many mulga trees (Acacia aneura), the leaves of which are fed to sheep in drought times.

The above condition should not be confused with the black livers found in a mutant strain of Corriedales in California. In these mutant sheep there is photosensitization following retention of
phyloerythrin. The darkening of the liver is due to melanin.

Special examination of the liver

When disease of the liver is suspected after a general clinical examination, special techniques of palpation, biopsy and biochemical tests of function can be used to determine further the status of the liver.

PALPATION AND PERCUSSION

In cattle, the liver is well concealed by the rib cage on the right-hand side and its edge cannot be palpated. A general impression of the size of the liver can be obtained by percussion of the area of liver dullness but accurate definition is not usually attempted. Deep percussion or palpation to detect the presence of hepatic pain can be carried out over the area of liver dullness in the posterior thoracic region on the right-hand side. Percussion over the entire area is necessary, as the pain of a discrete lesion may be quite localized.

If the liver is grossly enlarged in cattle, its edge can be felt on deep palpation behind the costal arch and the edge is usually rounded and thickened compared to the more defined edge of the normal liver. In cattle, the liver may be enlarged and palpable in advanced right-sided congestive heart failure, multiple liver abscesses and diffuse hepatitis. This type of palpation is relatively easy in ruminants but is unrewarding in horses and pigs because of the thickness of the abdominal wall and the shortness of the flank.

BIOPSY

Biopsy of the liver has been used extensively as a diagnostic procedure in infectious equine anemia, poisoning by Crotalaria spp. and other species of plants, and experimental work on copper and vitamin A deficiency. The technique requires some skill and anatomical knowledge.

The most satisfactory instrument is a long, small-caliber trocar and cannula to which is screwed a syringe capable of producing good negative pressure. The sharp point of the instrument is introduced in an intercostal space on the right-hand side (the number depending on the species) and advanced across the pleural cavity so that it will reach the diaphragm and diaphragmatic surface of the liver at an approximately vertical position. The point of insertion is made high up in the intercostal space so that the liver is punctured at the thickest part of its edge.

For example, in cattle the biopsy is made in the 11th intercostal space at a point on an imaginary line between the right elbow and tuber coxa. The instrument is rotated until the edge of the cannula approximates the liver capsule; the trocar is then withdrawn, the syringe is attached and strong suction is applied; the cannula is twisted vigorously and advanced until it reaches the visceral surface of the liver. If its edge is sufficiently sharp the cannula will now contain a core of liver parenchyma and if the instrument is withdrawn with the suction still applied a sample sufficient for histological examination and microassay of vitamin A, glycogen or other nutrient is obtained.

Details of the technique for cattle, sheep and horses are available. A disposable biopsy needle suitable for use in animals is available and a needle has also been designed that includes a device that ensures that the core of tissue in the cannula is in fact detached from the parenchyma of the organ.

A system to score liver biopsies as a prognostic aid in horses with suspected liver disease is highly reliable. Horses with scores of 0 or 1 were equally likely to survive up to 6 months with a combined mortality of 4%. Horses with biopsy scores between 2 and 6 had a combined mortality of 33% and were at a 12-fold increased risk of nonsurvival within 6 months compared to horses with a biopsy score of 0. Horses with biopsy scores between 7 and 14 had a combined mortality of 86% and were at a 46-fold increased risk of nonsurvival compared to horses with a biopsy score of 0. The evidence indicates that liver biopsy is the one antemortem test of greatest value in the absence of noninvasive tests that are able to reliably distinguish horses with significant liver disease from those without. Examination of liver biopsies may establish the presence of liver disease, provide a specific diagnosis, guide therapeutic choice and also help determine prognosis in cases of suspected liver disease.

Multiple liver biopsies can be done safely in neonatal calves from 4–28 days of age.

The major deficiency of the method lies in the sample that is obtained, and unless the liver change is diffuse the sample may not be representative. The procedure has been repeated many times on one animal without injury. The principal danger is that if the direction of the instrument is at fault it may approach the hilus and damage the large blood vessels or bile ducts. If the liver is shrunken or the approach too caudal no sample is obtained. Fatal hemoperitoneum may result if a hemorrhagic tendency is present and peritonitis may occur if the liver lesion is an abscess containing viable bacteria. Biliary peritonitis results if a large bile duct is perforated. It seems possible that the technique could precipitate a fatal attack of ‘black disease’, but many thousands of biopsies are performed without such an incident.

Compared to the human patient, who can voluntarily restrain respiratory movements, the animal patient will traumatize its diaphragm and liver if the needle is not withdrawn quickly.

MEDICAL IMAGING OF THE LIVER

ULTRASOUND

Ultrasonography of the liver is now being used as an aid to diagnosis of diseases of the liver of large animals. A complete ultrasonicographic assessment of the liver can provide detailed information about the size, position and parenchymal pattern of the liver. Ultrasonographic examinations of the liver of normal cattle and sheep have now been described and represent the basis for use of the technique in diagnosis of liver disease. In cattle, the liver, caudal vena cava, portal vein and gallbladder can be visualized. Ultrasonography is the only practical method for the diagnosis of thrombosis of the caudal vena cava.

Ultrasonicographic technique

Examination of the liver of cattle is done with a 3.5 MHz linear transducer on the right side of the abdomen while the cows are standing. The hair is clipped and the skin shaved between the sixth intercostal space and a hand’s breadth behind the last rib. After application of transmission gel to the transducer the cows are placed and examined, beginning caudal to the last rib and ending at the sixth intercostal space. Each intercostal space is examined dorsally to ventrally, with the transducer held parallel to the ribs. The texture and the visceral and diaphragmatic surface of the liver are scanned, and the hepatic and portal veins, caudal vena cava and biliary system are examined. Breed and age of cow does not influence the ultrasonicographic appearance of the liver, particularly position, size, and vasculature of the liver and gallbladder. During pregnancy, the diameter of the caudal vena cava increases slightly and that of the portal vein decreases. Ultrasonography has been used to detect thrombosis of the caudal vena cava in a cow with ascites and cholelithiasis in horses.

Percutaneous ultrasound-guided cholecystostomy in cows is an excellent method of obtaining samples of bile for demonstration of Fasciola hepatica and Dicrocoelium dendriticum eggs and for
Percutaneous ultrasound-guided portocentesis in cows is an excellent method for measuring the composition of hepatic portal blood and comparing it with peripheral blood.\textsuperscript{24}

Ultrasonography and digital analysis can be used for the diagnosis of hydropic degeneration of the liver of cows instead of biochemical analysis.\textsuperscript{8} Diffuse hepatocellular disease such as fatty liver in dairy cows can also be detected and evaluated.\textsuperscript{26} Ultrasonography has been used to evaluate the liver–kidney contrast in the diagnosis of fatty liver infiltration in dairy cattle.\textsuperscript{27}

Cholestasis
Cholestasis in cows can be diagnosed using ultrasonography (Fig. 7.2) to visualize dilatation of the extrahepatic and intrahepatic bile ducts, and dilatation of the gallbladder.\textsuperscript{28} The presence of jaundice and bilirubinuria combined with the ultrasonographic findings supports the diagnosis of jaundice due to obstruction.\textsuperscript{29}

Hepatic abscesses
Hepatic abscesses in cows and feedlot cattle can be visualized using ultrasonography.\textsuperscript{20,30} The abscesses may vary in location from the caudodorsal aspect of the liver in the 11th and 12th intercostal spaces to the cranioventral aspect of the liver in the sixth, seventh and eighth intercostal spaces.\textsuperscript{29} Those on the left side of the liver cannot be detected. The medical imaging of the abscesses was more sensitive than laboratory evaluation of liver tests, which was not useful.\textsuperscript{30} The diameter of the abscesses in cows may vary in size from 5–15 cm and the presence of the abscesses can be confirmed by centesis and aspiration of the contents.

**LABORATORY TESTS FOR HEPATIC DISEASE AND FUNCTION**

Hepatic disease is difficult to diagnose based on clinical findings alone and the use of laboratory tests is necessary. The results and interpretation of such tests, however, depend on the nature of the lesion, the duration and severity of the disease, and species variations. Specific tests that identify the exact nature of the lesion are not available, and a combination of tests is necessary to make a diagnosis. For example, it is suggested that testing for serum bile acids, arginase and gamma-glutamyl transferase (GGT) gives a sensitive indicator of cholestasis and/or hepatocellular necrosis, and a liver biopsy would form the minimum combination of tests for the diagnosis and prognosis of hepatic disease in the horse.\textsuperscript{31,32} Total serum bile acids, plasma glutamate dehydrogenase, GGT and liver biopsy are useful in the horse with liver disease.\textsuperscript{33} Based on experimentally induced liver disease in cattle, it is suggested that the serum activities of sorbitol dehydrogenase (SDH), GGT and aspartate aminotransferase (AST, formerly known as SGOT), and the BSP clearance test, provide sensitive indicators of hepatocellular injury in cattle.

All laboratory tests are aids to diagnosis and must be carefully interpreted in conjunction with clinical and other available data. This is particularly important in the laboratory investigation of liver disease in the horse.\textsuperscript{24} No one test will provide sufficient information, and a combination of tests is necessary. Depending on the time of sampling in relation to the pathological processes developing and the presence of complicating or secondary pathology, there may be elevations in alkaline phosphatase (ALP) and GGT. A horse with chronic hepatic lesions may have a leukocytosis and neutrophilia, hypoalbuminemia, hyperbilirubinemia, increased ALP and GGT and, depending on other factors, there may be increases in AST, SDH, total lactate dehydrogenase and others. None of these individual tests are specific for hepatic disease and there is no direct relationship between the magnitude of the serum enzyme level and the degree of liver injury. For these reasons, it is often necessary to take a liver biopsy.

The laboratory tests for the diagnosis of hepatic disease and to evaluate hepatic function in farm animals can be divided into those that measure:

- Excretory rate of parenterally administered substances such as BSP
- Ability of the liver to remove substances from the serum and detoxify them
- Serum levels of liver enzymes that increase following hepatic injury
- Indirect assessment of hepatic function such as blood glucose, serum proteins, clotting factors and urinalysis.

**HEPATIC FUNCTION**

The sulfobromophthalein sodium clearance test has been used in cattle, sheep, and calves.\textsuperscript{26,27} Lateral abdominal radiography can be used to determine the size and location of the liver in foals.\textsuperscript{27} Fluoroscopy and contrast media injected into the mesenteric vein have been used to detect the presence of portosystemic shunts in foals and calves.\textsuperscript{26,27}

![Fig. 7.2 Ultrasonogram and schematic of the liver in a cow with obstructive cholestasis due to fasciolosis. The intrahepatic bile ducts are dilated. Normally, they are not visible. The ultrasonogram was obtained from the 11th intercostal space of the right side using a 5.0 MHz linear transducer. 1 = Lateral abdominal wall; 2 = Liver; 3 = Dilated intrahepatic bile ducts. Ds, Dorsal; Vt, Ventral. (Reproduced with kind permission of U. Braun.)](image-url)
and horses, and although little information is available the test appears to have diagnostic value. The single injection technique has the advantage of being noninvasive, repeatable and suitable for conscious animals.** The time required by the normal liver to reduce the plasma concentration of BSP to half the initial concentration is taken as the standard BSP half-life and in cattle is 2.5–5.5 minutes, in sheep 2.0 minutes** and in normal horses about 2.0 minutes.** All horses with confirmed liver disease have a reduction in plasma BSP clearance against time.** The results are modified by the ability of the liver to excrete BSP via the biliary system and to store it in hepatocytes. Factors other than liver disease that increase the half-life significantly are starvation in horses, competition with bilirubin for excretory capacity, and youth, foals less than 6 months of age having a significantly slower clearance rate. Precise timing of samples is needed because of the rapid excretion rate.

In sheep, where severe hepatic dysfunction is accompanied by a steep rise in blood ammonia levels, and where this is reflected in the development of spongy degeneration in the brain, the level of glutamine in the cerebrospinal fluid is also elevated. Glutamine is a byproduct of the metabolism of amion in brain cells. Acute ammonia toxicity is manifested by tetany, ataxia and pulmonary edema, and affected animals are likely to die before the effects of subacute poisoning, hepatic encephalopathy, are seen.

**ICTERIC INDEX**

Measurement of the icteric index of plasma, by comparing its color with a standard solution of potassium dichromate, cannot be considered to be a liver function test but it is used commonly as a measure of the degree of jaundice present. The color of normal plasma varies widely between species depending upon the concentration of carotene. Horse, and to a less extent cattle, plasma is quite deeply colored, but sheep plasma is normally very pale. The color index needs to be corrected for this factor before the icteric index is computed. Hyperbilirubinemia occurs in many diseases of cattle and in most cases is related to a failure of the liver to remove unconjugated bilirubin from the serum rather than to a failure of the liver to excrete conjugated bilirubin.** The cause may be associated with anorexia, which resembles the hyperbilirubinemia associated with fasting in sick horses.

Adult cattle with hepatic disease do not consistently have high serum bilirubin concentrations and visible jaundice does not occur frequently in cattle with hyperbilirubinemia. Total bilirubin concentrations in adult cattle should be 0.4 mg/dL but young healthy calves may have mean concentrations 0.87 mg/dL and even higher, up to 1.7 mg/dL.** The use of high bilirubin concentrations as an indicator of liver disease in calves is unreliable because the sensitivity is only about 66%. This is similar to results in adult cattle in which serum bilirubin concentrations are neither a specific nor a sensitive test for chronic liver disease.

Persistent hyperbilirubinemia has been reported in a healthy Thoroughbred horse that was not related to feed intake and not associated with increased hemolysis or acquired hepatic disease.** Inappropriate conjugation of bilirubin rather than any abnormality in bilirubin uptake or excretion is considered a possibility similar to the human syndrome associated with a familial deficiency of bilirubin–uridine diphosphate glucuronyl transferase.

**SERUM HEPATIC ENZYMES**

The determination of serum levels of hepatic enzymes is used commonly for the detection and evaluation of hepatic disease. The interpretation of elevated values of enzymes in plasma is dependent not only on the tissue and site of origin but also on the half-time of clearance of the enzyme.

- **Sorbitol dehydrogenase** (also called t-iditol dehydrogenase (IDI)) is almost completely selective as an indicator of liver damage and is the preferred test for hepatic damage in sheep and cattle.
- **Lactate dehydrogenase** (LDH) is abundant in liver, kidney, muscle and myocardium.
- **Aspartate aminotransferase** or t-alanine aminotransferase (ALT, previously known as SGPT) are of some value as an indicator of liver damage because of their high content in liver but are generally considered to be too nonspecific to be of great diagnostic value.
- **Arginase** is a specific indicator of hepatic disease because it is not found in appreciable quantities in other organs. Arginase has a short blood half-life, which makes it useful for the diagnosis of acute hepatic disease but not for less severe forms.
- **Gamma-glutamyl transferase** is an enzyme widely distributed in a variety of equine tissues. Specific activity of GGT in the horse is highest in the kidney, pancreas and liver. Serum GGT activity is used as a diagnostic criterion for hepatobiliary diseases in cattle, sheep and horses. In the horse, increases in serum GGT may be associated with hepatocellular - damage and liver necrosis in a variety of natural and experimentally induced liver diseases. These include biliary obstruction, carbon disulfide toxicity, carbon tetrachloride toxicoses, cholestasis, iron hepatotoxicosis, Senecio poisoning and hyperlipidemia in ponies. GGT is a sensitive indicator of liver damage in horses affected with pyrrolizidine alkaloids in the early stages of the disease but values do not correlate with the increase in the severity of the lesions observed on liver biopsy samples collected later in the chronic phase of the disease.
- GGT has sufficient sensitivity (75%) and specificity (90%) to function as a primary screening test for subclinical liver disease in horses exposed to pyrrolizidine alkaloids. In horses that had consumed hay contaminated with Senecio vulgaris, the GGT values fluctuated widely: some horses with high levels did not die, whereas others had slight above reference values at the initial sample collection and died. GGT is a practical routine test for the evaluation of liver amyloidosis status in serum-producing horses.** In foals during the first month of life values were 1.5–3 times higher than the upper physiological reference values for healthy adult horses.** In neonatal foals, the serum ALP, GGT and SDH activities were increased during the first 2 weeks of life.

- **Glutamate dehydrogenase** (GD) occurs in high concentration in the serum of ruminants and horses with liver disease.
- **Ornithine carbamoyl-transferase** (OCT) levels are also elevated in chronic diseases, but only when there is active liver necrosis and not when the lesions are healing.
- **Alkaline phosphatase** levels are used as a test of hepatic excretory function in the horse and are of value in that species but variations in normal cattle have such a wide range that results are difficult to interpret. Of the tests available for testing of biliary obstruction the serum ALP test is preferred. However, there is a similar response to damage in other tissues.

**Hepatic enzyme profile according to species**

The serum hepatic enzymes considered to be most useful as an aid in the diagnosis of liver disease in the different species are as follows.

**Cattle**

In adult cattle, GGT, ALP, SDH, AST and GD are most useful in identifying
animals with chronic hepatic disease. The dehydrogenases (SDH and GD) have the shortest half-lives in serum and may not increase in cattle with chronic liver disease.

In the early stages of hepatic dysfunction in cattle, SDH is the most efficient and sensitive test. In the later stages when tests of biliary excretion are more applicable, estimations of serum bilirubin and BSP test are indicated.

Calves
In neonatal calves under 6 weeks of age, none of the common tests for assessment of liver damage or function in adult cattle are useful for detection of hepatic disease. The serum activity of most enzymes, total bilirubin concentration and sulfobromophthalein sodium clearance half-time are significantly higher in newborn calves than in 2-week-old calves. In calves less than 6 weeks of age with suspected liver disease, several tests should be used to assess liver damage, which includes GD activity and total serum bile acid concentration. The concentrations of direct bilirubin may be of more value than determination of total bilirubin for assessing liver damage. It is suggested that percutaneous liver biopsy may provide the most information.

Horses
The clinicopathological features of primary liver disease in the horse have been examined in several case studies. Total serum bile acids, GD, GGT and liver biopsy are helpful in studying different types of hepatic disease in the horse. In one series of primary hepatic disease all horses had high activities of serum GGT and most had high activities of serum GD and high concentrations of bile acids. Horses that were euthanized or died had significantly higher concentrations of GGT, GD and bile acids than survivors. Horses with signs of hepatic encephalopathy had plasma ammonia levels greater than 90 μmol/L but this was not correlated with the clinical severity of the disease. Half of the cases with hepatic encephalopathy were hyperglycemic, none was hypoglycemic, and none had abnormally low levels of plasma urea.

In a series of 82 cases in horses, 61 were confirmed to have significant liver disease and 12 were not. Only serum concentrations of GGT, globulins and ALP were found to be significantly different between the two groups of horses. Clinical and ultrasonographic data were found, when present, to be good indicators of the presence of liver disease.

The single positive test results of greatest diagnostic value were the presence of hepatic encephalopathy, increased GGT, hypoalbuminemia, increased ALP, increased total bile acids and increased total bilirubin. Increased AST and increased GD were also good diagnostic value but only when used in combination with the above tests. No single combination or sequential test was able to fully discriminate between horses with and without biopsy-confirmed liver disease and reliance on the use of noninvasive tests for the prediction of the presence or absence of significant liver disease may lead to frequent diagnostic errors. Certain positive results did reliably predict the presence of liver disease but negative test results were invariably unsatisfactory predictors of absence of liver disease.

In the early stages of hepatic dysfunction, SDH is preferred. Plasma ammonia concentrations may be significantly elevated compared to clinically normal horses but are not always accompanied by a decline in plasma urea concentration. A fall in plasma glucose concentration represents a poor prognosis.

The most useful noninvasive prognostic test in cases of suspected liver disease in adult horses is the severity of clinical signs.

**SERUM BILE ACIDS**

The concentration of total serum bile acids has been reported as a sensitive and specific indicator of hepatobiliary disease in humans and animals. Abnormalities of bile acid metabolism may be detectable in animals with liver disease that have little evidence of hepatic dysfunction as determined by other common liver function tests. Bile acids are the end-products of the metabolism of cholesterol by the liver. They are excreted in the bile and reabsorbed from the intestine either unchanged or after further transformation by bacterial action. In experimental chronic copper poisoning in sheep, the total bile acid concentration in the plasma is a more sensitive indicator of hepatic damage than the concentration of plasma bilirubin or the activity of transaminases. The rise in total serum bile acid concentration usually correlates well with the severity of liver disease. In cattle, there is extreme variability among all types and ages of animals and the variation is even greater in beef cattle than in dairy cattle. Values for calves 6 weeks of age and for 6-month-old heifers are significantly lower than values for lactating dairy cows. The 5th–95th percentile range of values (μmol/L) were:

- For beef cattle, 9–126
- For lactating dairy cattle, 15–88
- For 6-month-old heifers, 11–64.

In order to be specific for liver damage in cattle, the value determined for a single sample would have to be more than 126 μmol/L in beef cattle, or more than 88 μmol/L in lactating dairy cattle. There are hour-to-hour fluctuations in serum bile acid concentrations in cattle, which makes interpretation difficult. Feeding practices and stage of lactation can also affect the serum bile acid concentrations.

The serum bile acid concentrations in dairy cattle with hepatic lipidosis were compared with liver fat content and sulfobromophthalein (BST) half-life. Because of the large variability in serum bile acid concentrations in fed cows and the lack of correlation of measured values with liver fat content, bile acid determinations are not reliable as an indicator of subclinical hepatic lipidosis.

In cattle, total serum bile acids are more specific and sensitive indicators of a wide variety of hepatic disease and are significantly correlated with the degree of illness compared to other tests of hepatic function. Some diurnal variations in total serum bile acids occur in normal cattle. In horses, total serum bile acid concentrations are also a sensitive indicator of several hepatic diseases and are most useful when combined with other tests of hepatic disease.

**Blood ammonia levels**

The microbial deamination of amino acids in the intestinal tract is the major source of ammonia which is absorbed by the intestine into portal venous blood and converted into urea by the liver. The concentration of blood ammonia can be an indicator of functional hepatic mass. Generally, plasma ammonia concentration is a sensitive and specific indicator of hepatic disease in the horse, although it may fluctuate widely even on the same day and the concomitant low plasma urea concentration anticipated because of the liver's reduced synthetic ability is often not apparent.

In cattle with hepatic disease, plasma ammonia levels are significantly elevated compared to normal animals but not always accompanied by a decline in plasma urea concentrations. In healthy cattle, the plasma ammonia:urea concentration ratio is 9:1 and the plasma ammonia:glucose concentration 11:1. In hepatic disease, a plasma ammonia:glucose ratio 40:1 or plasma ammonia:urea ratio 30:1, particularly with a rising total ketone body concentration and a declining glucose concentration, represents a guarded prognosis.

Most cases of portosystemic shunts are accompanied by marked increases in blood ammonia levels. Careful handling of the blood samples is critical to obtain reliable results. Blood samples with species and preferably...
In diffuse diseases of the liver no general treatment is satisfactory and the main aim should be to remove the source of the damaging agent. The most that can be attempted in acute hepatitis is to tide the animal over the danger period of acute hepatic insufficiency until the subsidence of the acute change and the normal regeneration of the liver restores its function. Death may occur during this stage because of hypoglycemia, and the blood glucose level must be maintained by oral or intravenous injections of glucose. Because of the danger of guanidine intoxication an adequate calcium intake should be insured by oral or parenteral administration of calcium salts.

There is some doubt as to whether protein intake should be maintained at a high level, as incomplete metabolism of the protein may result in toxic effects, particularly in the kidney. However, amino acid mixtures, especially those containing methionine, are used with apparently good results. The same general recommendations apply in prevention as in the treatment of acute diffuse liver disease. Diets high in carbohydrate, calcium and protein of high biological value and a number of specific substances are known to have a protective effect against hepatotoxic agents.

In chronic, diffuse hepatitis fibrous tissue replacement causes compression of the sinusoids and is irreversible except in the very early stages, when removal of fat from the liver by the administration of lipotrophic factors including choline and maintenance on a diet low in fat and protein may reduce the depressive effects of fibrous tissue contraction. A high-protein diet at this stage causes stimulation of the metabolic activity of the liver and an increased deposit of fat, further retarding hepatic function.

Local diseases of the liver require surgical or medical treatment depending upon the cause, and specific treatments are discussed under the respective diseases.

## Diffuse diseases of the liver

### Hepatitis

The differentiation of hepatic diseases into two groups of hepatitis and hepatosis has not achieved general acceptance and nonspecific terms such as hepatic injury are used. The word hepatitis is used throughout this chapter to include all diffuse, degenerative and inflammatory diseases that affect the liver. It is used here also to include the common pathological classification of cirrhosis. Clinically the syndrome caused by fibrosis of the liver is the same as that caused by hepatitis and the etiology is the same, the only difference being that the onset of the disease is slower and less acute than in hepatitis.

## Etiology and Epidemiology

Although there is an extensive list of causes of hepatitis there are still a number of unknown factors. At least there are many sporadic cases of hepatic insufficiency, especially in horses, in which the cause is not determined. In most cases the clinical disease has an acute onset and a fatal outcome but the lesion is of a much longer duration.

In a case-control study of cases of equine hepatitis admitted to the Liphook Equine Hospital in the UK, ponies were more likely to develop hepatic disease than light riding horses but neither age nor gender were significant factors. Overall the case fatality was low (25.9%); horses with unclassified hepatopathies had the lowest fatality rate and horses with cholangiohepatitis, pyrrolizidine alkaloid toxicity and chronic active hepatitis had significantly higher fatality rates by comparison. None of age, breed or gender had any detectable effect on outcome.

In a series of 50 cases of equine primary hepatic disease in England, 37 cases were in ponies; 25 cases were caused by pyrrolizidine alkaloid toxicity and 11 cases classified as undifferentiated nonmegalocytic cirrhosis on the basis of histopathological findings.

The literature on primary liver disease in the horse has been reviewed.
between 1992 and 1997\textsuperscript{11} and the cause remains unknown.
- Severe cases of equine viral arteritis manifest signs of hepatitis
- Systemic mycoses, e.g. histoplasmosis, may be accompanied by multiple granulomatous lesions of the liver
- Other diseases in which hepatic lesions may be common at necropsy, but in which there are no overt signs of clinical disease during life. Some of these are infectious equine anemia, salmonellosis, septicemic listeriosis, leptospirosis in aborted foals\textsuperscript{11}
- Infectious necrotic hepatitis associated with Clostridium novyi has been described in a 9-year-old mare.\textsuperscript{13}

**Parasitic hepatitis**
- Acute and chronic liver fluke infestation
- Migrating larvae of Ascaris sp.
- Fibrosing granulomas of liver in horses with chronic shistosomiasis\textsuperscript{14}
- Hepatic sarcocystosis in a horse.\textsuperscript{15}

**Nutritional hepatitis (trophopathic hepatitis)**
Selenium and vitamin E deficiency are factors in dietary hepatic necrosis in pigs. A multiple dietary deficiency has also been suggested as the cause of a massive hepatic necrosis observed in lambs and adult sheep on trefoil pasture in California. Hepatic lipoidis and hyperlipemia occurs most commonly in pregnant Shetland pony mares on a falling plane of nutrition.\textsuperscript{16} The fat cow syndrome occurs in beef and dairy cattle following mastitis or metritis; it is thought that the hepatic dysfunction may have been the result of endotoxemia.\textsuperscript{7} The same position applies in hepatitis associated with extensive tissue damage occurring after burns, injury and infarction.

**Infectious hepatitis**
Diffuse hepatic lesions in animals are rarely associated with infectious agents. The significant ones are:
- The virus of Rift Valley fever
- Bacillus piliformis, associated with Tyzzer's disease in foals
- The equid herpesvirus 1 of viral rhinopneumonitis as a cause of abortion in horses
- Deltaproteobacterium associated with epizootic abortion of cattle in California
- Postvaccinal hepatitis of horses, also known as serum hepatitis.

**Idiopathic acute hepatic disease, Theliler's disease and acute liver atrophy**, is the most common cause of acute hepatic failure in the horse.\textsuperscript{8} The disease is commonly associated with the administration of biologics of equine origin, usually tetanus antitoxin.\textsuperscript{9}

A series of four fatal cases of serum hepatitis associated with the administration of commercial plasma in the horse has been reported.\textsuperscript{10} The prevalence in one veterinary teaching hospital has been recorded as 0.4%\textsuperscript{10}

A large number of cases of equine hepatic encephalopathy occurred in France with increased iron stores in the parenchymal cells of the liver. Hepatic fatty cirrhosis (hard yellow liver) in sheep and cattle has occurred in isolated areas of western and southern Texas during years of maximal rainfall.\textsuperscript{19} The cause is unknown but the high incidence during periods of heavy rainfall suggests the possibility of either a mycotoxin or nutritional deficiency.\textsuperscript{20}

**Congestive hepatopathy**
Increased pressure in the sinusoids of the liver causes anoxia and compression of surrounding hepatic parenchyma. Congestive heart failure is the common cause and leads to centrilobular degeneration.

Inherited hepatic insufficiency occurs in Southdown and Corriedale sheep (see Ch. 34, Inherited photosensitization).

**Portosystemic vascular anomaly**
Portosystemic shunts in large animals have been recorded occasionally in foals and calves.\textsuperscript{12,21} There is altered blood flow through the liver and hepatic insufficiency secondary to hepatic atrophy.

**PATHOGENESIS**
Hepatitis may be associated with a number of agents but the clinical effects are approximately the same in all instances as described under clinical manifestations earlier in the chapter. The usual lesion in toxoplastic hepatitis is centrilobular and varies from cloudy swelling to acute necrosis, with terminal occlusive lesion in some plant poisonings. If the necrosis is severe enough or repeated a sufficient number of times, fibrosis develops. The effects of endotoxin on the liver include multifocal hepatocellular necrosis, decreased hepatic gluconeogenesis and decreased hepatic blood flow.\textsuperscript{7} It is possible that endotoxin may cause the Kupffer cells to release lysosomal enzymes, prostanoids and collagenase, which can damage hepatocytes. Endotoxen not detoxified by the Kupffer cells may interact directly with the hepatocytes, causing lysosomal damage and decreased mitochondrial function, leading to necrosis. In infectious hepatitis the lesions vary from necrosis of isolated cells to diffuse necrosis affecting all or most of the hepatic parenchyma.

**Serum hepatitis in the horse**
This is characterized by severe central lobular necrosis following the administration of biologics of equine origin such as tetanus antitoxin, commercial equine plasma and other products.\textsuperscript{10}

**In parasitic hepatitis** the changes depend upon the number and type of migrating parasites. In massive fluke infestations sufficient damage may occur to cause acute hepatic insufficiency, manifested particularly by submandibular...
edema. In more chronic cases extension from a cholangitis may also cause chronic insufficiency.

Trophopathic hepatitis is characterized by massive or submassive necrosis. Hepatic lipidosis is characterized by fatty infiltration of hepatocytes progressing to development of fatty cysts.

Congestive hepatitis is characterized by dilatation of central veins and sinusoids with compression of the parenchymal cells. Hepatic fibrosis develops particularly if there is massive hepatic necrosis that destroys entire lobules. Degeneration is not possible, as it is when the necrosis is zonal, and fibrous tissue replacement occurs. Thus fibrosis is a terminal stage of hepatitis that may have developed acutely or chronically and is manifested by the same clinical syndrome as that of hepatitis except that the signs develop more slowly. Fibrosis may also develop from a cholangitis.

The term cirrhosis has been avoided because it carries connotations from human medicine that may be misleading when applied to animals. Hepatic fatty cirrhosis occurs in sheep and cattle and is characterized at necropsy by ascites, hydropericardium and acquired hepatic vascular shunts. There is progressive fatty change of the liver leading to cirrhosis. Fibrosis begins in the pericentral zone associated with ruptured fatty cysts and continues until there is widespread bridging pericentral fibrosis. No lesions of hepatic encephalopathy occur.

In portosystemic vascular anomalies the increased levels of ammonia, short-chain fatty acids and amino acids in the peripheral circulation are the cause of the depression and neurological abnormalities that are typical of hepatic encephalopathy. These high levels of metabolites are the result of failure of the hepatic metabolism and detoxification of substances absorbed from the intestines, which are normally delivered to the liver via the portal vein before they enter the peripheral circulation.

Liver disease and liver failure

The liver has vast reserves of function, an almost embryonic capacity to regenerate itself, and it can perform adequately despite often extensive pathological damage to its integrity. This is best exemplified in liver abscesses in cattle, where rarely is clinical disease evident in the presence of large abscesses.

Liver disease is usually diagnosed by identifying clinical signs produced by failure of some of its functions. There is often liver disease prior to failure of function and laboratory tests may detect disease before there is actual failure. The liver has a reserve of about 70-80% and this must be compromised before some of its functions fail. Some functions fail before others, which explains the progression of clinical signs.

Intravascular hemolysis in equine liver disease

Intravascular hemolysis with prominent hemoglobinuria has occurred in horses with severe and advanced liver disease. Neutrophil hypersegmentation of undetermined cause was present in one horse with liver disease and intravascular hemolysis.

CLINICAL FINDINGS

The cardinal signs of hepatitis are anorexia, mental depression — with excitement in some cases, muscular weakness, jaundice and in the terminal stages somnolence, recencymbug and coma with intermittent convolution. Hemoglobinuria is also a variable sign in horses. The hemolytic crisis with which it is associated is always a precursor to a fatal outcome. Animals that survive the early acute stages may show photosensitization, a break in the wool or hair leading to shedding of the coat and susceptibility to metabolic strain for up to a year.

The clinical findings of hepatic disease in the horse are generally nonspecific but the most useful noninvasive prognostic test in cases of suspected liver disease in adult horses is the severity of clinical signs. Regardless of the cause, consistent clinical findings include weight loss, anorexia, dullness and depression. Other findings include jaundice, tachycardia, intermittent fever, abdominal pain, ventral body wall edema, clotting deficiency, muscle fasciculations and diarrhea or constipation. Jaundice is a constant feature in acute hepatic necrosis. Dysphagia, photosensitization, encephalopathy and hemorrhages tend to occur terminally, particularly in horses with cirrhosis. In chronic liver disease, the course is several months.

The initial anorexia is often accompanied by constipation and punctuated by attacks of diarrhea. The feces are lighter in color than normal and if the diet contains much fat there may be steatorrhea.

In a series of 50 cases of primary hepatic disease in horses, the following occurrence of clinical signs was observed (%): dull demeanor (68); anorexia (56); abdominal pain (50); encephalopathy (50); weight loss (50); jaundice (42); abnormal intestinal motility (42); abnormal fecal consistency (28); dehydration (18); photosensitization (16); bilateral laryngeal paralysis (14); clinical coagulopathy (10); dermatitis and pruritus (8); peripheral edema (6); oral ulceration (6); tenesmus (4); penile prolapse (2); and rectal impaction (2).
I

PART 1 GENERAL MEDICINE

Chapter 7: Diseases of the liver and pancreas

become immobile and die in a state of coma. Morbidity may reach 80–100% and mortality varies from 10–60%. Mortality increases during each succeeding month following October, climaxes in January and February, and then decreases in the months thereafter.

Portosystemic shunts

In young animals with portosystemic shunts the clinical findings include stunted growth, ascites and variable neurological abnormalities resulting from hepatic encephalopathy. Calves and foals may be a few weeks to a few months of age before they are presented for examination. Apparent cortical blindness, circling and dementia are common. Persistent tenesmus is common in calves. Recurrent episodes of unexplained neurological clinical findings in a young foal suggest the presence of a portosystemic shunt. A tentative diagnosis may be made using clinicopathological results but a definitive diagnosis requires portovenography. Blood ammonia levels are markedly increased and serum bile acids are also increased but the serum levels of hepatic derived enzymes may be normal.

CLINICAL PATHOLOGY

The clinicopathological features of primary liver disease have been examined and are summarized in the section dealing with laboratory tests for hepatic disease and function.

Scoring liver biopsies of the horse with suspected liver disease is highly predictive of the severity of the lesion and of prognosis.

In a series of 82 cases in horses, 61 were confirmed to have significant liver disease and 12 were not. Only serum concentrations of GGT, globulins and ALP were found to be significantly different between the two groups of horses.

Clinical and ultrasonographic data were found, when present, to be good indicators of the presence of liver disease.

The single positive test results of greatest diagnostic value were the presence of hepatic encephalopathy, increased GGT, hypoalbuminemia, increased ALP, increased total bile acids and increased total bilirubin. Increased AST and increased GD were also good diagnostic value but only when used in combination with the above tests. No single combination or sequential test was able to fully discriminate between horses with and without biopsy-confirmed liver disease and reliance on the use of noninvasive tests for the prediction of the presence or absence of significant liver disease may lead to frequent diagnostic errors. Certain positive results did reliably predict the presence of liver disease but negative test results were invariably unsatisfactory predictors of absence of liver disease.

The most useful noninvasive prognostic test in cases of suspected liver disease in adult horses is the severity of clinical signs. A significantly poorer prognosis was found in association with clinical signs suggestive of liver disease, presence of hepatic encephalopathy, ultrasonographic abnormalities, increased globulins, increased total bile acids, increased ALP, increased GGT, erythrocytosis, leukocytosis, low serum albumin and low serum urea. The literature on liver disease in the mature horse has been reviewed.

NECROPSY FINDINGS

The liver in hepatitis is usually enlarged and the edges swollen but the appearance of the hepatic surface and cross-section varies with the cause. In acute toxic and trophotropic hepatitis the lobulation is more pronounced and the liver is paler and redder in color. The accentuation of the lobular appearance is caused by engorgement of the centrilobular vessels or centrilobular necrosis. There may be accompanying lesions of jaundice, edema and photosensitization. In infectious hepatitis the lesions are inclined to be patchy and even focal in their distribution. Parasitic hepatitis is obviously traumatic, with focal hemorrhages under the capsule and the necrosis and traumatic injury definable as tracks. Congestive hepatitis is marked by severe enlargement of the liver, a greatly increased content of blood and marked accentuation of the lobular pattern caused by vascular engorgement and fatty infiltration of the parenchyma. In hepatic fibrosis the necropsy findings vary widely depending on the causative agent, the duration of its action and on its severity. The liver may be grossly enlarged or be much reduced in size with marked lobulation of the surface.

Hepatic encephalopathy associated with portosystemic shunt is characterized by spongiform changes and gliosis of white matter in all levels of the brain.

The liver may be of normal size or small and firm, with a prominent reticular pattern visible on the capsular and cut surfaces, and the portal veins may be absent.

TREATMENT

The principles of treatment of hepatitis have already been outlined. Results are seldom good. Protein and protein hydrolysates are probably best avoided because of the danger of ammonia intoxication. The diet should be high in carbohydrate and calcium and low in protein and fat, but affected animals are usually completely anorectic. Because of the failure of detoxification of ammonia and other nitrogenous substances by the damaged liver and their importance in the production of nervous signs, the oral administration of broad-spectrum antibiotics has been introduced in humans to control protein digestion and putrefaction. The results have been excellent with neomycin and chlorotetracycline, the disappearance of hepatic coma coinciding with depression of blood ammonia levels. Purgation and enemas have also been used in combination with oral administration of antibiotics but mild purgation is recommended to avoid unnecessary fluid loss. Supplementation of the feed or periodic injections of the water-soluble vitamins are desirable. Hepatic fibrosis is considered to be a final stage in hepatitis and treatment is not usually undertaken.

DIFFERENTIAL DIAGNOSIS

Hepatitis is easily misdiagnosed as an encephalopathy unless jaundice or photosensitization is present. The nervous signs are suggestive of:

- Encephalomyelitis
- Encephalomalacia
- Cerebral edema

Congestive hepatitis is usually not manifested by nervous signs and, being a secondary lesion in congestive heart failure, is usually accompanied by ascites and edema in other regions and by signs of cardiac involvement. Hepatic fibrosis may produce ascites without evidence of cardiac disease.

Acute diseases affecting the alimentary tract, particularly engorgement on grain in cattle and horses, may be manifested by signs of nervous derangement resembling those of acute hepatic dysfunction but the history and clinical examination usually suggest a primary involvement with the alimentary tract. Anorectic hepatic insufficiency may be mirrored by an adenocarcinoma of the pancreas, which is unlikely to be diagnosed during life.

REFERENCES

Focal diseases of the liver

HEPATIC ABSCESS

Local supplicative infections of the liver do not cause clinical signs of hepatic dysfunction unless they are particularly massive or extensively metastatic. They do cause significant losses in feedlot and grain-fed cattle because of the frequency of ruminitis in those cattle leading to hepatic abscess formation and the rejection of the affected livers at the abattoir. In feedlot cattle in North America the incidence of liver abscesses averages about 16% but ranges from about 8% to 40% or even higher, up to 78%.

In a 2-year study of bovine hepatic abscessation in 10 abattoirs in Ireland, the livers of 6337 12–16-month-old heifers were examined. The frequency of gross lesions was 5.8%, of which 1.9% had abscesses. Only 1.17 had scarring, and 0.7% telangiectasis. Of the livers with abscesses, 44% had a single large abscess, 35% had a single small abscess and 19% had more than two abscesses; in 16% the abscesses were resolving and in 8.3% the abscesses were ruptured. A total of 43% of the livers with abscesses had adhesions to the diaphragm and diaphragmatic lung lobes, 2.5% had adhesions to other abdominal organs, 10% also had scarring and 1.7% also had lesions attributable to the liver fluke. Clinical signs attributable to the abscesses were observed in only one animal.

Cattle started on feed in November and January in North America, and cattle housed in confinement or outside with overhead shelter, had higher incidences of liver abscesses. Virginiamycin at 16.5–19.3 mg/kg DM in the diet reduced the incidence of liver abscesses in feedlot cattle. Occasional cases occur in dairy cows and cause severe illness. The toxemia of traumatic hepatitis is usually due to toxins from Arcanobacterium pyogenes, Streptococcus and Staphylococcus spp. and Fusobacterium necrophorum, which are implanted in the lesions by the perforating foreign body; of the F. necrophorum isolates most will be of the A biotype, although the B biotype does occur usually in combination with other bacteria.

Hepatic abscesses in goats have been described. Out of 658 necropsies of goats, 2.5% had hepatic abscesses. The abscesses occurred most commonly in adults. All the affected animals were in poor bodily condition. The organisms isolated included Corynebacterium pseudotuberculosis (58.9%), Escherichia coli (11.8%), Corynebacterium spp. (11.8%), Mannheimia haemolytica (5.0%), Proteus sp. (5.9%) and Staphylococcus aureus (5.9%).

Omphalophlebitis, ruminal para-keratosis or ruminitis may also lead to hepatic invasions by F. necrophorum or other organisms and abscessed livers are common in cattle fed heavily on concentrates. Black disease is a profound toxemia caused by the liberation of potent exotoxin from C. novyi. Clostridium sordellii is associated with hepatic abscesses in neonatal lambs and bacillary hemoglobinuria by a toxin from Clostridium haemolyticum with focal hepatic necroses. A focal bacterial hepatitis, identified as 'Tyzer's disease' and associated with Bacillus piliformis, and yersiniosis associated with Yersinia pseudotuberculosis are listed elsewhere. Occasional cases of strangles that develop bacteremia spread may also develop hepatic abscesses, as may septicaemia in lambs associated with Histophilus somni.

The fungus Mortierella wolffii has been isolated from a liver abscess in a cow in Australia. The liver abscess was grossly indistinguishable from other common bacterial abscesses, such as those associated with A. pyogenes or F. necrophorum.

The clinical signs of these specific diseases are included under the discussion of each disease and the only finding common to all is local pain on palpation or percussion over the liver.

A most important relationship is that between liver abscess and caudal vena caval syndrome. Sudden death, or any death, of cattle due to pulmonary hemorrhage should be examined with this possibility in mind. Liver abscesses have been produced experimentally in cattle by injecting F. necrophorum into the hepatic portal vein. They are characterized by an elevation of blood levels of sialic acid and mucoprotein. High concentration of alpha-1 acid glycoprotein (α1-AG) present in naturally occurring cases is correlated with sialic acid concentration.

Hepatic abscesses in horses

Hepatic abscesses in horses are characterized clinically by a history of weight loss, fever, inappetence and depression. The etiology and pathogenesis are unknown. Clinicopathological abnormalities are consistent with a diagnosis of chronic bacterial infection such as leukocytosis with a mature neutrophilia, thrombocytosis, hypergbulinemia, hypalbuminemia and a markedly decreased albumin-to-globulin concentrations ratio. Ultrasonography is a useful diagnostic aid. Secondary immune-mediated complications may develop in young adult horses with hepatic abscesses. The prognosis is very unsatisfactory, in spite of intensive antibiotic and supportive therapy, and euthanasia is recommended.

TELANGIECTASIS OF THE BOVINE LIVER (‘SAWDUST LIVER’)

Telangiectasis of the bovine liver accounts for about 10% of all bovine liver condemnations in federally inspected slaughter facilities in the USA. Condemnation is based on aesthetics. The lesion is usually easily diagnosed by inspectors but its biological significance is undetermined. Affected livers contain more bacteria than normal livers but telangiectasis cannot be linked to an infectious process. In some affected livers, E. coli O157 was present, which is a potential zoonotic risk. It is believed that E. coli O157 in meat at slaughter is an external contaminant and, experimentally in cattle, there is no evidence that the organism translocates from the alimentary tract to deeper tissues. The morphological, immunohistochemical and ultrastructural studies of pretelangiectasia and telangiectasia of the bovine liver have been examined.
cause clinical signs. A primary hepatic fibrosarcoma in a goat has caused loss of body weight, although appetite was maintained, anemia and jaundice. Hepatic biliary cystadenoma has been described in a 10-year-old horse. It is regarded as a morphological variant of biliary cystadenoma of domestic animals.

A series of 66 primary hepatic tumors of cattle has been examined and classified using modern criteria. Fifty hepatocellular tumors (10 adenomas and 40 carcinomas), 10 cholangiocellular tumors, two cavernous hemangiomas, two hemangioendothelial sarcomas, one fibroma and one Schwannoma were diagnosed. An association with cirrhosis was not found. A bile duct hamartoma in a calf has been reported.

DISEASES OF THE BILIARY SYSTEM

Cases of biliary tract disease with clinical manifestations are uncommon in food animals and horses. Occasional cases of cholangitis occur in cattle and horses. Associated clinical signs include fever, pain over the liver, jaundice and photosensitization. There is usually an accompanying leukocytosis and a left shift. In horses a sequel to cholangitis may be a diffuse bacterial hepatitis with signs of hepatic insufficiency. Septic cholangiohepatitis and cholangiocarcinoma have been recorded in a horse.

Concretions in the biliary system of cattle are usually a sequel to fascioliasis. Mild cases show anorexia and pain over the liver. Severe cases show recurrent attacks of severe abdominal pain, alimentary tract stasis and pain on percussion over the liver. Jaundice occurs only in the terminal stages of fatal cases and is accompanied by recumbency, depression and coma. The frequency of pigment gallstones is high in sheep and associated with high total bilirubin concentration in the bile. Other causes of biliary tract disease include gallbladder empyema and a bile duct carcinoma. In the latter case there was severe loss of body weight and signs referable to metastases in other organs but there were no clinical or post-mortem signs of biliary malfunction. Biliary atresia in young foals is manifested by an early period of normality for 2–3 weeks after birth followed by the development of listlessness, anorexia, the passage of gray, pasty feces and jaundice. Death occurs about a week later.

Obstructive cholelithiasis in horses may cause intermittent colic or continuous pain and sometimes jaundice. A series of 10 cases in horses has been reported. Clinical findings included fever, icterus, mild intermittent colic and weight loss. Laboratory findings included leukocytosis, hyperproteinemia and hyperfibrinogenemia. GGT and lactate dehydrogenase were also elevated.

Cholangiohepatitis in horses
A series of nine cases was reported of cholangiohepatitis and cholelithiasis in mature horses with a median age of 13 and a range of 4–18 years. Clinical signs that prompted referral of each horse to a veterinary teaching hospital included anorexia, depression, weight loss, colic, intermittent fever and icterus. In all horses, the GGT and ALP were elevated, and there was hyperbilirubinemia. Trans-abdominal ultrasonography was used to evaluate the size and nature of the liver and to obtain liver biopsy for histopathology and culture. The ultrasonographic findings included increased hepatic echogenicity, hepatomegaly, enlarged distended bile ducts and occasional calculi as the salient features. Neutrophilic cholangiohepatitis consistent with an infectious cause was a feature of biopsy material from each horse.

The etiology and pathogenesis of cholangiohepatitis and cholelithiasis in horses is uncertain. Retrograde bacterial infection from the small intestine is considered probable. Culture of liver biopsy material yielded E. coli and Bacteroides vulgatus from only a small number of affected animals. Long-term parenteral Gram-negative antibiotics daily for a median of 51 days (range 17–124) was associated with survival in 7/9 horses. Supportive intravenous fluid therapy is also necessary. Progress can be monitored by evidence of clinical improvement and declining levels of GGT.

Cholangiohepatitis in a 2-month-old calf was characterized clinically by depression, fever and diarrhea. There was marked leukocytosis and neutrophilia. The GGT and ALP were markedly elevated and total bilirubin was elevated. Ultrasonographic examination of the liver revealed gross abnormality and liver biopsy results indicated neutrophilic hepatitis and multifocal hyperplasia of the biliary epithelium suggesting cholangiohepatitis. Culture of liver tissue yielded E. coli sensitive to amikacin, cefazolin and ceftiofur. Supportive fluid therapy and antibiotics may be successful.

Supportive cholangiohepatitis and cholelithiasis associated with enteritis has been described occurring in adult horses. Clinical findings included nonresistant colic, fever, depression, severe abdominal pain, tachycardia, dehydration, gastric fluid accumulation and absence of abdominal sounds over all four quadrants. Distended loops of small intestine were palpable on rectal examination and the peritoneal fluid was serosanguinous. Azotemia, hyperbilirubinemia, increased ALP and GGT were present and persisted for several days. Cases were associated with severe inflammation of the small intestine and hypotensive shock.

Cholangiohepatitis and pancreatitis secondary to gastroduodenal ulceration in a 2-month-old foal was characterized clinically by colic unresponsive to surgical treatment. At necropsy, gastric ulceration, segmental duodenal stenosis and severe chronic cholangiohepatitis and pancreatitis were present.

Cholelithiasis attributable to a foreign body in a horse is recorded. Clinical signs suggestive of biliary disease in adult horses may be due to neoplasia of the pancreas (see below). A case of congenital hepatic fibrosis in a newborn calf is recorded.

REFERENCES

Diabetes mellitus
Lesions of the pancreas causing diabetes mellitus are recorded in cows and horses and donkeys. The clinical syndrome in horses includes weight loss, polydipsia, polyuria, polyphagia, ketosis, and loss of body condition that was present in only 3 of 18- and 23-year-old horses with biliary ultrasonography in a 2-month-old foal. Pancreatic disease in large animals is rare and only a few comments are presented here.

DIABETES MELLITUS

Lesions of the pancreas causing diabetes mellitus are recorded in cows and horses and donkeys. The clinical syndrome in horses includes weight loss, polydipsia, polyuria, polyphagia, ketosis, and loss of body condition that was present in only 3 of 18- and 23-year-old horses with biliary ultrasonography in a 2-month-old foal. Pancreatic disease in large animals is rare and only a few comments are presented here.
polyuria, intense hyperlipidemia and high blood levels of cholesterol, triglycerides and glucose. Clinical observations suggest that the disease is most likely to occur in old horses and may be due to pancreatic injury related to migration of strongyle larvae. Diabetes mellitus resulting from pancreatic beta-cell failure is rare in the horse but has been reported in a domesticated Spanish Mustang. In cows there is afebrile emaciation, polydipsia, ketonuria, glucosuria and hyperglycemia.

**PANCREATIC ADENOCARCINOMA**

The pancreatic duct of the horse is anatomically close to the common bile duct and it is not unexpected that a tumor mass should cause a syndrome of biliary duct pathology, although there is a surprising absence of jaundice at some stages of the disease. There is emaciation, concomitant moderate abdominal pain and variable fecal texture up to diarrhea. GGT and blood ammonia levels are greatly increased.

**PANCREATIC ADENOMA**

Convulsions due to hypoglycemia have been recorded in a pony with a pancreatic adenoma. It is assumed that the hypoglycemia resulted from hyperinsulinism generated by the beta-cell adenoma.

**PANCREATITIS**

Pancreatitis is rare in farm animals. Inflammatory and degenerative changes are detected post mortem in some cattle but are rarely diagnosed clinically because of a lack of clinical and laboratory findings. Ultrasonographic imaging of experimentally induced pancreatitis in cattle has been described.

Causes of cardiovascular dysfunction

- Cardiac arrhythmia
- Obstructed flow
- Regurgitant flow
- Contractile dysfunction (systolic failure)
- Inadequate filling (diastolic filling)
- Loss of blood

It is usual to divide heart failure into two types, acute heart failure and chronic (congestive) heart failure. However, a complete range of syndromes occurs and some of them do not fit neatly into one or other category. Circulatory equilibrium is not maintained when cardiac output is deficient. If this develops sufficiently slowly, compensatory mechanisms, plus the failure of the heart itself as a pump, result in an increase in venous pressure and congestive heart failure. If on the other hand there is an acute reduction of cardiac output, as is caused by sudden cessation of the heart beat, the effect is to deprive tissues of their oxygen supplies and the syndrome of acute heart failure develops.

Heart failure can be left-sided, right-sided or both left-and right-sided. Left-sided heart failure causes an increase in left ventricular end-diastolic pressure, mean left atrial pressure and pulmonary venous pressure. Depending upon the magnitude and rate of the increase in pressure, left-sided heart failure results in left ventricular end-diastolic pressure, mean left atrial pressure and pulmonary venous pressure.

Acute heart failure causes an increase in right ventricular end-diastolic pressure, mean right atrial pressure and jugular venous pressure. Depending upon the magnitude and rate of the increase in pressure, right-sided heart failure results in symmetric venous distension (most readily detected in the jugular veins), an increase in pleural, pericardial and abdominal fluid (ascites), and hepatomegaly.

CIRCUIT FAILURE

In circuit failure the effective blood volume is decreased because of loss of fluid from the vascular system (hypovolemic shock) or by pooling of blood in peripheral vessels and increased capillary permeability (maldistributive shock). The failure of venous return results in incomplete filling of the heart and a reduction in cardiac output, although there is no primary defect in pump performance. The effects of circuit failure are the same as those of chronic (congestive) heart failure in that the supply of nutrients to the tissues and the removal of waste products from the tissues are reduced.

CARDIAC RESERVE AND COMPENSATORY MECHANISMS IN HEART FAILURE

The normal heart has the capacity to increase its output severalfold in response to normal physiological demands created by exercise and to a lesser extent by pregnancy, lactation, digestion and hot ambient temperatures. Collectively, these compensatory responses comprise the cardiac reserve. Similar compensatory responses are utilized by the failing heart in an attempt to maintain cardiac output.
Cardiac reserve and its response in heart failure have not been studied extensively in large domestic animals and consequently its description must rely heavily on studies on cardiac failure in small domestic animals and studies of the effect of exercise on cardiovascular performance in the horse.\(^1\) Clinical observations on cardiac insufficiency and cardiac failure in large animals suggest that the processes are very similar to those in small animals and humans.

The major mechanisms whereby the blood flow to an organ can be increased are:

- Increase in heart rate
- Increase in stroke volume
- Redistribution of blood flow to vital organs, or organs with particularly high metabolic requirements.

All of these mechanisms act synergistically and are interrelated. Heart rate and stroke volume are the determinants of cardiac output (cardiac output is the product of heart rate and stroke volume).

**CARDIAC RESERVE AND HEART RATE**

There is a great deal of cardiac reserve in the heart rate, and an elevation of heart rate alone is a significant factor in increasing cardiac output in the exercising horse. There is a limitation to heart rate reserve because with increasing heart rates there is a decrease in diastolic filling time, and stroke volume falls at excessive heart rates. Effective heart rate reserve can be increased with exercise training, and maximum heart rate in trained exercising horses is six to seven times resting values.\(^7\) This large increase in heart rate reflects the metabolic scope of trained horses. In contrast, cattle can only increase their heart rate to two or four times their resting values. An increase in heart rate is also used to maintain cardiac output by the failing heart. With cardiac insufficiency in the horse and the cow it is rare for the heart rate to exceed 120/min, and rates higher than this are frequently due to tachyarrhythmias that require immediate treatment.

**CARDIAC RESERVE AND STROKE VOLUME**

Stroke volume is variable and depends upon the amount of shortening that the myocardial fibers can attain when working against arterial pressure. It is determined by an interplay of four factors:

- Ventricular distending or filling pressure (preload)
- Contractility of the myocardium (inotrophic state)
- The tension that the ventricular myocardium must develop during contraction and early ejection (afterload)
- The sequence of atrial and ventricular depolarization.

An increase in ventricular distending pressure (end-diastolic pressure or volume) will increase ventricular end-diastolic fiber length, which, by the Frank–Starling mechanism and stretch-dependent calcium sensitization, will result in increased stroke work and a larger stroke volume. Ventricular distending pressure is influenced by atrial contraction and is greatly augmented by increased venous return associated with exercise and increased sympathetic activity. Contractility is most influenced by adrenergic activity and circulating catecholamines. An increase in stroke volume is achieved primarily by an increase in the ejection fraction and a reduction in the end-systolic volume but can also be achieved by a decrease in afterload, which is primarily a function of aortic or pulmonary impedance (the resistance and reactance of the vasculature to ejection).

**CARDIAC RESERVE AND MIXED VENOUS OXYGEN TENSION**

In normal animals at rest, the oxygen tension of mixed venous blood is above 40 mmHg (5.3 kPa), which represents a considerable reserve. Increased extraction of oxygen from the blood by various tissues, with a subsequent decrease in mixed venous oxygen tension and a corresponding increase in arterial venous oxygen difference, occurs during exercise and in pump and circuit failure.\(^4\) In uncompensated heart failure, where stroke volume is reduced, the mixed venous oxygen tension falls below 40 mmHg, reaching 15–25 mmHg in severe shock states, and the arterial venous oxygen difference is large. There is also a redistribution of blood flow to vital organs. In the horse the splenic storage capacity for erythrocytes is large and the spleen may contain one-third of the total red cell volume. Maximal emptying of the spleen under adrenergic activity can significantly influence the oxygen-transporting capacity of the blood and, in the horse, the splenic reservoir contributes significantly to cardiovascular reserve.

**CARDIAC RESERVE AND AUTONOMIC NERVE ACTIVITY**

It is evident that increased sympathetic nerve activity also plays a significant role in compensating for the failing ventricle, but one that is not readily determined clinically. An increase in sympathetic activity acts to augment cardiac output by increasing the heart rate, by improving the contractility of the myocardium and by augmenting venous return to the heart. Autonomic nerve activity also regulates blood flow to more essential organs even when faced with insufficient cardiac output.

**CARDIAC RESERVE IN CARDIAC INSUFFICIENCY**

In cardiac insufficiency the principal defect is in the contractile state of the myocardium, and ventricular performance at any given end-diastolic volume or pressure is diminished. In early failure, cardiac output may still be maintained in the normal range by an increase in filling pressure and, through utilization of stretch-dependent calcium sensitization and the Frank–Starling principle, the ventricles can eject a normal stroke volume despite the depression in contractility. Thus, early in the course of cardiac failure, the end-diastolic pressure may be elevated only during periods with heavy demands on the heart, such as during exercise. However, as myocardial function becomes increasingly impaired, this mechanism is increasingly utilized for lesser work demands until end-diastolic pressure is elevated even at rest or with normal activity.

Ventricular filling pressure is augmented by increased venous return associated with contraction of the venous capacitance vessels under increased sympathetic tone, and by an increase in blood volume as the result of salt and water retention by the kidney. Decreased renal perfusion results in the release of renin by the juxtaglomerular cells in the kidney and the activation of the renin–angiotensin–aldosterone system. Renin causes the conversion of angiotensinogen to angiotensin I and angiotensin I in turn is converted to angiotensin II in the lungs. Angiotensin II is a powerful vasoconstrictor and promotes the effect of norepinephrine. Angiotensin II also stimulates the release of aldosterone from the adrenal cortex, which acts to increase sodium retention by the kidney with consequent expansion of the interstitial fluid and blood volumes.

Although the increase in ventricular end-diastolic pressure acts to maintain cardiac output, it is associated with a marked increase in systemic or pulmonary venous pressure, producing secondary effects that result in many of the clinical abnormalities associated with congestive heart failure. Where the contractile state of the heart is markedly reduced, the increased end-diastolic pressure is unable to maintain normal stroke volume, even at normal activity, and cardiac output is reduced even at rest – the state of uncompensated heart failure, which is clinically manifest as pump failure.
MEASUREMENT OF CARDIAC RESERVE
From a clinical standpoint it would be desirable to be able to detect incipient cardiac insufficiency at a very early stage.

A clinical estimation of cardiac reserve based on physical examination is important when a prognosis is to be made for an animal with heart disease. Some of the important criteria used in making this assessment include the heart rate, the intensity of the heart sounds, the size of the heart, the characteristics of the pulse and the tolerance of the animal to exercise. A resting heart rate above normal indicates loss of cardiac reserve. The absolute intensity of the heart sounds suggests the strength of the ventricular contraction, soft sounds suggesting weak contractions and sounds that are louder than normal suggesting cardiac dilatation and possibly hypertrophy, although this is a very crude and insensitive measure. The interpretation of variation in intensity must be modified by recognition of other factors, such as pleural and pericardial effusion, that interfere with audibility of the heart sounds.

Pulse characteristics are of value in determining the cardiac reserve but they are greatly affected by factors other than cardiac activity. An increased amplitude of the pulse occurs when the cardiac stroke volume is increased, but a decreased amplitude may result from reduced venous return as well as from reduced contractile power of cardiac muscle.

Exercise tolerance is an excellent guide to cardiac reserve and the least expensive and most practical method for quantifying cardiovascular reserve. Exercise tolerance is best assessed by measuring the maximum heart rate attained after a standard exercise test, and the speed with which the heart rate returns to normal.1,3,4

CARDIAC ENLARGEMENT
The ratio of heart weight to body weight is greater in athletic animals than in nonathletic animals, and the heart:weight ratio in horses can be modestly increased during training as a result of physiological hypertrophy. Cardiac enlargement is also a compensatory response to persistent increased workloads that are associated with cardiovascular disease. The heart may respond by dilatation, hypertrophy or a combination of both.

Cardiac hypertrophy (concentric hypertrophy) is the usual response to an increased pressure load, and there is hypertrophy of individual fibers with an increase in the number of contractile units (sarcomeres) and an increase in total muscle mass. However, cardiac hypertrophy is usually accompanied by decreased capillary density and increased intercapillary distance and, in states of cardiac insufficiency, coronary blood flow reserve places limitations on this compensatory mechanism.

Cardiac dilatation (eccentric hypertrophy) is the usual response to an increased volume load and probably results from fiber rearrangement. Contractions occurring in a dilated chamber can eject a larger volume of blood per unit of myocardial shortening. However, the limitation to this compensatory mechanism is evident in the law of Laplace, which shows that in the dilated chamber greater myocardial wall tension is required to produce an equivalent elevation of intrachamber pressure during ejection.

The significance of finding cardiac enlargement on clinical examination is that it indicates the presence of a significant volume or flow load on the heart, or the presence of myocardial disease and a reduction of cardiac reserve. The detection of cardiac enlargement on physical examination is aided by careful auscultation of the heart, palpation of the apex beat and rarely by thoracic percussion. A palpable and audible increase in the apex beat and area of audibility, backward displacement of the apex beat, increased visibility of the cardiac impulse at the base of the neck and behind the elbow and increased area for the cardiac shadow during thoracic percussion are all suggestive of cardiac enlargement. Care must be taken that the abnormalities observed are not due to displacement of the heart by a space-occupying lesion of the thorax such as thymic lymphosarcoma, or to collapse of the ventral part of the lung and withdrawal of lung tissue from the costal aspects of the heart. Echocardiography should be used to quantify the magnitude of the enlargement whenever the results of physical examination suspect the presence of cardiac enlargement.

Manifestations of circulatory failure
The manifestations of circulatory failure depend on the rapidity of its onset, the magnitude of its severity, and on its duration. Chronic (congestive) heart failure and acute heart failure are discussed below.

CHRONIC (CONGESTIVE) HEART FAILURE

Etiology Diseases of the endocardium, myocardium and pericardium that interfere with the flow of blood into or away from the heart, or that impair myocardial function, may result in congestive heart failure.

Clinical findings Generalized venous distension and edema in right-sided failure. Pulmonary edema and respiratory distress in left-sided failure.

Clinical pathology Increased serum concentration of cardiac troponin I, a cardiac-specific enzyme.

Necropsy findings Subcutaneous edema, ascites, hydrothorax and hydropericardium; enlargement and engorgement of the liver with right-sided failure. Pulmonary edema with left-sided failure.

Diagnostic confirmation Clinical Treatment Treatment of specific cause, often unsuccessful. Diuretics, salt restriction, minimize activity, possibly digoxin.

ETIOLOGY Causes of chronic (congestive) heart failure can be broadly characterized as follows.

Valvular disease
- Endocarditis resulting in either valvular stenosis or valvular insufficiency
- Congenital valvular defects – most commonly valvular stenosis
- Rupture of valve or valve chordae.

Myocardial disease
- Myocarditis – bacterial, viral, parasitic or toxic
- Myocardial degeneration – nutritional or toxic
- Congenital or hereditary cardiomyopathy
- Toxins affecting cardiac conduction.

Congenital anatomical defects producing shunts
- Cardiac defects, such as ventricular or atrial septal defects, tetralogy of Fallot
- Vascular abnormalities producing shunts, such as patent ductus arteriosus.
Hypertension
- Pulmonary hypertension – high altitude disease, cor pulmonale
- Systemic hypertension – undocumented cause of congestive heart failure in large animals.

Pressure load
Pressure loads occur with lesions that produce an obstruction to outflow such as aortic or pulmonary valve stenosis, where the heart is required to perform more work to eject an equivalent amount of blood. Pressure loads are not necessarily associated with lesions in the heart. For example, pulmonary hypertension, such as occurs in high altitude disease of cattle due to an increase in pulmonary vascular resistance, may result in cardiac insufficiency. In general, the left ventricle can tolerate a pressure load to a much greater extent without overt signs of cardiac insufficiency than the right ventricle.

Volume load
Volume loads (flow loads) occur commonly with both acquired and congenital heart defects. In aortic valve insufficiency and mitral valve insufficiency the volume of blood delivered to the tissues does not differ significantly from normal. However, in order to achieve a normal cardiac output, the forward stroke volume of the ventricle is markedly increased and the heart is much more inefficient for the same amount of effective work. In a similar manner a patent ductus arteriosus or an interventricular septal defect with a large left-to-right shunt of blood can place a considerable flow load on the left ventricle. In general, the right ventricle is more capable of sustaining a flow load than the left ventricle.

Pumping defects (systolic failure)
Cardiac insufficiency may occur without any increase in workload if there is a primary weakness in the myocardium or defect in its rhythmic and coordinated contraction. Myocarditis, cardiomyopathy and neoplasms of the heart, especially bovine viral leukosis lesions of the right atrium, are the common causes. Arrhythmias are a rare cause of congestive heart failure but a common cause of acute heart failure.

Filling defects (diastolic failure)
Pericardial diseases such as pericarditis and pericardial tamponade can result in cardiac insufficiency by interfering with diastolic filling. Filling of the ventricle is determined by the complex interaction of a number of factors, including mean circulatory filling pressure, mean right atrial pressure, stiffness of the ventricular chamber (which is determined, in part, by mean arterial blood pressure) and the pressure gradient across the ventricular wall. The latter is markedly affected by increases in pericardial fluid pressure that are present in pericarditis and pericardial tamponade.

PATHOGENESIS
Cardiac reserve and compensatory mechanisms in heart failure are described in the preceding section. In the early stages of cardiac disease circulatory equilibrium may be maintained. However, cardiac reserve is reduced and the animal is not able to cope with circulatory emergencies as well as a normal animal. This is the stage of waning cardiac reserve in which the animal is comparatively normal at rest but is incapable of performing exercise – the phase of poor exercise tolerance – or responding appropriately to a physiological stressor such as late gestation or being housed in hot ambient temperatures. Congestive heart failure develops when these compensatory mechanisms reach their physiological limit and the heart is unable to cope with the circulatory requirement at rest.

Failure may manifest as primarily being right-sided, left-sided or both left- and right-sided. Many of the clinical signs that appear during the development of cardiac insufficiency, as well as those associated with uncompensated heart failure, are the consequence of congestion or edema due to increased venous hydrostatic pressure. A decreased cardiac output also contributes to the clinical signs by the production of tissue hypoxia.

Right-sided congestive heart failure
Venous congestion is manifest in the systemic circulation. The increase in mean right atrial pressure increases the mean capillary pressure and the net force for filtration of fluid across the capillary bed is therefore greatly increased. This results in the production of edema in dependent subcutaneous body areas and in body cavities. In the kidneys the increase in hydrostatic pressure is offset by the reduced flow of blood and urine output is reduced. The increased back pressure to the glomerulus causes increased permeability and escape of plasma protein into the urine. Venous congestion in the portal system is an inevitable sequel of hepatic congestion and is accompanied by impaired digestion and absorption and terminally by diarrhea.

Left-sided congestive heart failure
Increased pulmonary venous pressure results in venous congestion, decreased compliance of the lung and an increase in respiratory rate, an increase in the work of breathing, and exercise intolerance. Similarly, bronchial capillary congestion and edema result in encroachment on airways and a decrease in ventilatory efficiency. Where venous hydrostatic pressure is exceptionally high, the net force for filtration of fluid across the pulmonary capillary bed is greatly increased. This can result in pulmonary edema, with the presence of fluid around the septal vessels and in the alveolar spaces accompanied by marked impairment of gas exchange. The development of clinically detectable pulmonary edema depends to some extent on the rapidity of the onset of cardiac failure. In chronic failure syndromes, the development of a capacious lymphatic drainage system limits the occurrence of clinical pulmonary edema and, in large animals, pulmonary edema is usually limited to acute heart failure where there is a relatively sudden onset of a volume load on the left ventricle.

CLINICAL FINDINGS
The specific findings on auscultation and other examinations are described under the specific causes of congestive cardiac failure.

In the very early stages when cardiac reserve is reduced but decompensation has not yet occurred there is respiratory distress on light exertion. The time required for return to the normal respiratory and pulse rates is prolonged. In affected animals there may be evidence of cardiac enlargement and the resting heart rate is moderately increased. There may be a loss of body weight.

Right-sided congestive heart failure
The heart rate is increased and there is venous distension and subcutaneous edema. The superficial veins are engorged. In ruminants there is subcutaneous edema occurring in the brisket region, under the jaw and along the ventral midline, and ascites as indicated by the presence of an abdominal fluid wave on ballottement with palpation and less frequently by the presence of abdominal distension with a pear-shaped abdomen. Ascites needs to be differentiated from other causes of abdominal distension, and the detection by palpation per rectum of viscera floating in a fluid medium and the presence of a fluid wave on abdominal ballottement are highly suggestive of ascites. Care must be taken to differentiate ascites from uraemia and hydrops conditions of the uterus. Hydrothorax and hydropericardium may also be clinically detected in animals with ascites. In horses, edema is initially more prominent in the abdominal region between the front limbs, the ventral abdominal wall, the prepuce and the limbs. Ruminants and camels do not get edema in their legs in right-sided heart failure because
their comparatively thicker skin acts as an antigravity suit ('G' suit), minimizing the extent of hydrostatic pooling of blood in the limbs.

The liver is enlarged and, in cattle, may be palpable, protruding beyond the right costal arch with a thickened and rounded edge. In both horses and cattle liver enlargement may be detected by ultrasound examination. The respiration is deeper than normal and the rate may be slightly increased. Urine flow is usually reduced and the urine is concentrated and contains a small amount of protein. The feces are usually normal at first but in the late stages diarrhea may be evident. Body weight may increase because of edema but the appetite is poor and condition is lost rapidly. Epistaxis may occur in the horse but is rare in other species. The attitude and behavior of the animal is one of listlessness and depression; exercise is undertaken reluctantly and the gait is shuffling and staggery through weakness.

Left-sided congestive heart failure
The heart rate is increased and there is an increase in the rate and depth of respiration at rest, with cough, the presence of crackles (discontinuous sounds) at the base of the lungs and increased dullness on percussion of the ventral borders of the lungs. Terminally there is severe dyspnea and cyanosis.

The prognosis in congestive heart failure varies to a certain extent with the cause but in most cases in large animals it is poor to grave. The possibility of recovery exists with an arrhythmia, pericardial tamponade or pericarditis, but when the epicardium, myocardium or endocardium are involved complete recovery rarely if ever occurs, although the animal may survive with a permanently reduced cardiac reserve. Uncomplicated defects of rhythm occur commonly in the horse and these defects are more compatible with life than are extensive anatomical lesions.

CLINICAL PATHOLOGY
Clinicopathological examinations are usually of value only in differentiating the causes of congestive heart failure and in differentiating from other diseases. Aspiration of fluid from accumulations in any of the cavities may be thought necessary if the origin of the fluid is in doubt. The fluid is an edematous transudate except in pericardial tamponade (serosanguinous) or pericarditis (effusion) when it may be septic or nonseptic. In most cases protein is present in large amounts because of leakage of plasma from damaged capillary walls. Proteinuria is often present because of pressure-induced damage to the glomeruli. The serum concentration of cardiac troponin I provides an excellent cardiac biomarker in large animals, providing a sensitive and persistent indicator of cardiac injury.

NECROPSY FINDINGS
Lesions characteristic of the specific cause are present and may comprise abnormalities of the endocardium, myocardium, pericardium, lungs or large vessels. Space-occupying lesions of the thorax may constrict the cranial vena cava and interfere with venous return. The lesions that occur in all cases of congestive heart failure, irrespective of cause, are pulmonary congestion and edema if the failure is left-sided; anasarca, ascites, hydrothorax and hydropericardium and enlargement and engorgement of the liver, with a ‘nutmeg pattern of congested red centers of liver lobules surrounded by paler fatty peripheral regions, if the failure is right-sided. It is important to characterize the heart failure as being left-sided, right-sided or both left- and right-sided at necropsy, because this information will help in prioritizing the likely cause.

Differential diagnosis
- Causes of edema
- Causes of dyspnea

TREATMENT
The treatment of animals with clinical signs of congestive heart failure due to pericarditis or pericardial tamponade focuses on removing the pericardial fluid and preventing its return. In animals with pump failure, the treatment of congestive heart failure initially focuses on the reduction of the effects of increased preload by administering diuretic agents and restricting sodium intake, reducing the demands on cardiac output by restricting activity, and improving contractility by the administration of positive inotropic agents such as cardiac glycosides.

Diuretics
Diuretic treatment, furosemide, acetazolamide or chlorothiazide, is an important component of treatment in that it mobilizes and eliminates excess body fluids. Furosemide is most commonly used because it is the most potent diuretic available, is inexpensive and pharmacokinetic parameters have been determined for large animals. Furosemide should be administered at an initial intravenous dose of 0.25–1.0 mg/kg for horses and 2.5–5.0 mg/kg for cattle for the treatment of congestive heart failure. Multiple doses of furosemide will induce a hypokalemic, hypochloremic metabolic alkalosis, so it is important to monitor serum potassium and chloride concentrations during treatment. Access to free salt should be stopped, although it is usually impractical to formulate a salt-restricted diet.

Stall rest
Stall rest in a thermoneutral environment is also an important treatment requirement. Parturition may be electively induced in late gestation in order to prevent intrauterine fetal hypoxia and abortion, and to decrease the additional demand placed by placental blood flow on the cardiac output.

Cardiac glycosides
Digoxin is the most commonly used cardiac glycoside. In horses it can be administered either intravenously or orally but in ruminants it must be given intravenously or after induction of esophageal groove closure because digoxin is destroyed in the rumen. Digoxin should not be given intramuscularly in any species as it causes severe muscular necrosis and this is also reflected in erratic plasma digoxin concentrations following intramuscular administration. Treatment with digoxin results in an increase in cardiac contractility and a decrease in heart rate with increased myocardial oxygen consumption, increased cardiac output and a decrease in cardiac size. The improvement in cardiac output promotes diuresis and the reduction and elimination of edema.

The half-life of digoxin in the horse is 17–23 hours and a plasma therapeutic range for digoxin of 0.5–2.0 ng/mL has been suggested. Pharmacokinetic studies suggest that therapeutic but nontoxic plasma concentrations of digoxin in the horse will be achieved by an initial intravenous loading dose of 1.0–1.5 mg/100 kg followed by a maintenance dose of 0.5–0.75 mg/100 kg every 24 hours. In the horse the bioavailability of powdered digoxin given orally is low, being less than 20% of the administered dose. An oral loading dose of 7 mg/100 kg, followed by a daily oral maintenance dose of 3.5 mg/100 kg is suggested by pharmacokinetic studies.

The half-life of digoxin in cattle is 5.5–7 hours, requiring more frequent dosing than in horses, and an initial intravenous loading dose of 2.2 mg/100 kg followed by 0.34 mg/100 kg every 4 hours has been suggested. An alternative is to give digoxin as a continual infusion at 0.086 mg/100 kg. There is no established dose for digoxin administration in sheep but the half-life is similar to that in cattle.

No dosing regimen is absolute and the dose may need adjustment based on clinical response, evidence of toxicity, or by measuring the plasma digoxin concentration.
concentration. Dose rates other than those above have been used successfully.\textsuperscript{11,12} Toxicity with digoxin treatment is reported and may occur because the clearance of digoxin in some animals with congestive heart failure differs from that of normal animals on which the suggested doses have been based.\textsuperscript{13}

If treated animals are not eating, the daily oral administration of KCl (cattle 100 g, horses 30 g) is recommended\textsuperscript{5} and it is recommended that serum potassium concentrations be monitored because the toxic effects of digoxin are impacted by the serum potassium concentration. Because of the necessity for frequent dosing in cattle and the ineffectiveness of oral treatment, digoxin therapy has major limitations in ruminants, especially since the primary pathology that leads to congestive heart failure in cattle is commonly not correctable. Unless myocardial damage is transient, administration of the digoxin in all species will probably have to be continued for life, and this is rarely practical.

**REVIEW LITERATURE**

**REFERENCES**

**ACUTE HEART FAILURE**

**ETIOLOGY**

Acute heart failure can occur when there is a severe defect in filling, when there is failure of the heart as a pump, either due to severe tachycardia, bradycardia or arrhythmia, and where there is a sudden increase in workload. The sudden occurrence of tachyarrhythmias in association with excitement and severe enough to cause acute heart failure presumably results from the exacerbating influence of catecholamines.\textsuperscript{1,2} These are released in association with episodes of excitement and act to heighten the discharge potential of ectopic excitable foci associated with myocardial disease.

Acute heart failure can also occur in the absence of primary cardiac disease under the influence of pharmacological agents that affect cardiac conduction. These are associated with the ingestion of certain poisonous plants.

The many causes of acute heart failure are listed in greater detail under myocardial diseases. Some examples are as follows:

- Disorders of filling
- Pericardial tamponade – atrial and ventricular rupture
- Acute and pulmonary artery rupture
- Tachyarrhythmia
- Myocarditis, e.g. encephalomyocarditis virus, foot-and-mouth disease
- Nutritional deficiency myopathy, e.g. copper or selenium deficiency
- Plant poisoning, e.g. Phalaris spp., white snout root
- Electrocuton and lightning strike
- Bradyarrhythmia
- Iatrogenic, e.g. intravenous calcium gluconate or borogluconate administration, xylazine, tolazoline, concentrated solutions of potassium chloride
- Plant poisoning, e.g. Taxus spp.
- Increase in workload
- Rupture of aortic valve
- Acute anaphylaxis.

Arrhythmias and cardiac arrest may occur during the induction of anesthesia with barbiturates in the horse and may also occur without premonitory signs in horses under halothane anesthesia.

**PATHOGENESIS**

With excessive tachycardia the diastolic period is so short that filling of the ventricles is impaired and cardiac output is grossly reduced. In ventricular fibrillation no coordinated contractions occur and no blood is ejected from the heart. The cardiac output is also seriously reduced when the heart rate slows to beyond a critical point because cardiac output is the product of heart rate and stroke volume, and stroke volume cannot be markedly increased. In all these circumstances there is a precipitate fall in cardiac output and a severe degree of tissue ischemia. In peracute cases the most sensitive organ, the brain, is affected first and the clinical signs are principally neurological. Pallor is also a prominent sign in acute heart failure because of the reduction in blood flow.

In less acute cases respiratory distress is more obvious because of pulmonary edema and although these can be classified as acute heart failure they are more accurately described as acute congestive heart failure.

**CLINICAL FINDINGS**

The acute syndrome may occur while the animal is at rest but commonly occurs during periods of excitement or activity. The animal usually shows dyspnea, staggering and falling, and death often follows within seconds or minutes of the first appearance of signs. There is marked pallor of the mucous. Although chronic convulsions may occur they are never severe and consist mainly of sporadic incoordinate movements of the limbs. Death is usually preceded by deep, asphyxial gasses. If there is time for physical examination, weakness or absence of a palpable pulse and bradycardia, tachycardia or absence of heart sounds are observed. The specific findings in the heart and vascular system depend upon the arrhythmia and are detailed in the section on arrhythmias later in this chapter.

Horses with sudden onset of tachyarrhythmias due to atrial fibrillation or multiple ventricular extrasystoles, or with rupture of the aortic or mitral valve chordae show a syndrome where sudden onset of respiratory distress is the prominent manifestation. However, examination of the heart will allow a diagnosis of the underlying cause.

Acute heart failure is the cause of death in a significant proportion of horses that die suddenly and unexpectedly during training or racing.\textsuperscript{3} The diagnosis is based primarily on the findings of significant pulmonary hemorrhage and edema, although myocardial pathology is absent in most cases. Severe arrhythmic disturbances secondary to pre-existing myocardial injury and the concurrent presence of catecholamines, hyperkalemia and metabolic acidosis are likely causes.
CLINICAL PATHOLOGY

In general, there is insufficient time available in which to conduct laboratory tests before the animal dies. The demonstration of elevated serum troponin I concentrations, a sensitive and specific marker of myocardial damage, strongly supports the presence of myocardial disease. Laboratory tests may also be used to elucidate the specific etiology.

NECROPSY FINDINGS

In typical acute cases engorgement of visceral veins may be present if the attack has lasted for a few minutes but there may be no gross lesions characteristic of acute heart failure. Microscopic examination may show evidence of pulmonary congestion and early pulmonary edema. In more prolonged cases, venous engorgement with pulmonary congestion and edema are evident along with hydrothorax but these are more accurately described as acute congestive heart failure. The primary cause may be evidenced by macroscopic or microscopic lesions of the myocardium.

Differential Diagnosis

Acute heart failure should always be a major consideration as a cause of sudden and unexpected death in large animals, especially when death is associated with exertion or excitement. Acute heart failure may be mistaken for primary disease of the nervous system but is characterized by excessive bradycardia or tachycardia, pallor of mucosae, weakness or absence of the pulse and the mildness of the convulsions. Epilepsy and narcolepsy are usually transient and repetitive and have a characteristic pattern of development.

TREATMENT

Treatment of acute heart failure is not usually possible or practical in large animals because of the short course of the disease. Deaths due to sudden cardiac arrest or ventricular fibrillation while under anesthesia can be avoided to a limited extent in animals by external or internal cardiac compression or electrical conversion–stimulation but these techniques are generally restricted to sophisticated institutional surgical units. Also, the electrical energy required for defibrillation of animals larger than a sheep or goat is beyond the capabilities of conventional defibrillators unless the paddles are placed directly across the pericardium or transvenous electrodes are used. Intracardiac injections of very small doses of epinephrine in conjunction with external cardiac compression by jumping up and down on the thorax with the knees can be tried, with occasional success.

REFERENCES

Special examination of the cardiovascular system

The more commonly used techniques of examination of the heart and pulse are described in Chapter 1. A more detailed clinical examination of the system that gives greater attention to nuances of location and intensity of heart sounds and arterial and venous pulse characteristics is conducted whenever cardiovascular disease is suspect.

Special techniques of examination are also available which may be of value in some cases. With the exception of jugular venous pressure measurement, assessment of exercise intolerance, electrocardiography and indirect methods for measuring arterial blood pressure, many of these techniques have limited applicability in general practice as they require sophisticated and expensive equipment. The use of specialized diagnostic equipment is generally confined to teaching hospitals and investigative units.

PHYSICAL EXAMINATION

In the examination of animals suspected to have heart disease, it is important to determine the rate, rhythm and intensity of the individual heart sounds and the rate, rhythm and amplitude of the arterial pulse, examine for the presence of venous pulsation at the jugular inlet, and identify the point of maximal intensity and timing of murmurs within the cardiac cycle.

Heart Sounds

In the horse it is not uncommon to hear four heart sounds on auscultation, whereas two to three heart sounds are heard in ruminants and camels.

First heart sound

The first heart sound (S1) signals the onset of ventricular systole, is synchronous with the apex beat and is temporally associated with closure of the mitral and tricuspid valves. The area for maximal audibility of the mitral valve in the horse is on the left fifth intercostal space, at a level midway between a horizontal line drawn through the point of the shoulder and one drawn at the sternum at the caudal edge of the triceps muscle. With cattle, sheep, goats and swine the sound is located at a similar level but at the fourth intercostal space. The area for maximal audibility of the tricuspid valve is on the right side of the chest slightly ventral to the equivalent level for the mitral valve and at the fourth intercostal space in the horse; and at the level of the costochondral junction at the third intercostal space for other species.

Second heart sound

The second heart sound (S2) is associated with aortic and pulmonic valve closure and is synchronous with the end of systole and the beginning of diastole. The aortic component is most audible just ventral to a horizontal line drawn through the point of the shoulder and in the left fourth intercostal space in horses and the left third in the other species. The pulmonic component is most audible ventral and anterior to the aortic valve area in the left third intercostal space in horses and the left second or third intercostal space close to the costochondral junction in other species. These two components of the second heart sound have the same temporal occurrence on auscultation but tonal differences can frequently be detected at the two areas of maximal audibility. Splitting of the second sound in the horse can be detected on phonocardiographic examination but cannot be detected on auscultation and there is no respiratory-associated splitting, as occurs with some other species.

Third heart sound

The third heart sound (S3) is associated with rapid filling of the ventricle in early diastole and is heard as a dull thudding sound occurring immediately after the second sound. It is usually most audible on the left side just posterior to the area of maximal audibility of the first heart sound. However it is frequently heard over the base and also over the area of cardiac auscultation on the right side. Phonocardiographically there are two components to this heart sound but these are not usually detectable on clinical auscultation.

The third heart sound is very common in horses and can be detected in the majority of fit racing animals. It is more audible at heart rates slightly elevated above resting normal. The third heart sound is very common in slightly excited cattle (heart rates 80–100 beats/min) but becomes more difficult to hear when the heart rate exceeds 100 beats/min.

Fourth heart sound

The fourth heart sound (S4) is associated with atrial contraction. It is also called the ‘a’ sound. It occurs immediately before the first heart sound and is a soft sound most audible over the base of the heart on the left- and right-hand side. It is also common in horses but its clear separation from the first heart sound is dependent...
upon the length of the P-R interval, which varies between horses. At resting heart rates the S4 sound is detectable on clinical examination in at least 60% of horses.

The interval between the S4 and S1 frequently varies in the same horse at rest in association with variation in the P-Q interval and results in a clear separation in some beats with slurring of the two sounds together in other beats. The fourth heart sound or a split S1 is also commonly heard in young cattle, but phonocardiographic studies have not been undertaken.

Sequence of heart sounds
The sequence of heart sound occurrence is thus 4–1–2–3. The intensity of the third and fourth sounds is less than that of the first and second and the complex can be inaudible in association with variation in the P-Q interval and results in a clear separation in some beats with slurring of the two sounds together in other beats. The fourth heart sound or a split S1 is also commonly heard in young cattle, but phonocardiographic studies have not been undertaken.

Variation in heart sound intensity
Change in the intensity of the generation of sound by the heart or change in the transmission of the sounds between the heart and the stethoscope can result in variation in the intensity of heart sounds normally heard on auscultation.

- A decrease in the intensity of heart sound generation occurs in disease where there is poor venous return and decreased strength of cardiac contractility, such as in terminal heart failure, in hypocalcemia in cattle or in circulatory failure in all species.
- Conversely the intensity of the heart sounds may increase with anemia, cardiac hypertrophy and metabolic diseases such as hypomagnesemia. However, the intensity of the heart sounds is most often increased by sympathetic activation as a result of exercise, fear and excitement.

Muffling of the heart sounds suggests an increase in tissue and tissue interfaces between the heart and the stethoscope. This can be due to a shift in the heart due to displacement by a mass, changes in the pericardium (increased fluid or fibrous tissue), changes in the pleural space or increased subcutaneous fat. Heart sounds are detectable by auscultation on the left side in animals of all condition scores but heart sounds may become inaudible on the right side where the condition score approaches 5/5.

Heart rate
The relative temporal occurrence and the intensity of the third and fourth heart sounds changes with heart rate. At moderately elevated heart rates the third heart sound becomes more audible. At faster heart rates the third sound may merge and sum with the fourth sound or the fourth sound may merge with the first sound if the P-R interval decreases. During periods of a rapid change in heart rate, such as during the increase in rate that occurs following sudden noise or similar stimuli in excitable horses or the subsequent decrease in rate, the variation in the occurrence and the intensity of the third and fourth sound coupled with the variation in intensity of the first and second sound during this change can give the impression of a gross arrhythmia. Such impressions should be ignored if they occur only at times of rapid change of rate that is obviously induced by external influences and if there is no arrhythmia at the resting rate or the intervening stable elevated rate. Examination of the pulse during these periods of rapid change is also of value.

Variations in the intensity of the individual heart sounds or complete absence of some of them can occur in conduction disturbances and arrhythmic heart disease and can provide valuable clinical information. In several of these disturbances there is variation in the intensity of the first and third heart sounds associated with variation in the time of the preceding diastolic period and variations in diastolic filling. The intensity of the first heart sound may also vary with variations in the P-R interval or where there is complete atrioventricular dissociation. In several of the arrhythmias there is absence of one or more of the heart sounds. These findings are detailed below under the specific abnormalities.

EXAMINATION OF THE ARTERIAL PULSE
In arrhythmic heart disease the arterial pulse should be examined in more detail than that applied during routine clinical examination.

Pulse rate
The pulse rate should be examined over a period to determine if there is any sudden change in rate such as can occur with a shift in pacemaker to an irritable myocardial focus. At some stage during the examination of animals with tachyarrhythmias the heart rate and pulse rate should be taken synchronously to
determine the presence of a pulse deficit (auscultation of S1 but a weak or absent S2 accompanied by a weak or absent pulse). A convenient artery for this purpose is located on the posterior medial aspect of the radius and carpus in the horse and cow. However, the best artery to determine the pulse rate, rhythm and amplitude is the descending aorta; this artery should be palpated during rectal examination in horses and cattle.

Pulse rhythm
Pulse rhythm is carefully examined. When a 'dropped pulse' or arrhythmia is detectable the pulse the basic underlying rhythm should be established in order to determine if the heart is under regular pacemaker influence. This is best done by mentally or physically tapping out the basic rhythm of the heart and continuing this rhythm when irregularity occurs. With conditions such as second-degree heart block where there is a basic underlying rhythm initiated by the sinoatrial node, it is possible to tap through the irregularity and re-establish synchrony with the pulse. However, in conditions such as atrial fibrillation where there is no regular pacemaker it is not possible to establish any basic rhythm. This examination of rhythm can alternatively be conducted by auscultation and allows an immediate categorization of the arrhythmia into one of the two basic groups, those superimposed on a regular pacemaker influence (occasionally irregular) and those in which there is no regular pacemaker (irregularly irregular).

Amplitude
The amplitude of the pulse should also be carefully examined. Variations in pulse amplitude are associated with those arrhythmias that produce a variation in diastolic filling period within the heart. The extreme of this is a pulse deficit (decrease in intensity or absence of a pulse associated with heart sounds).

EXAMINATION OF THE JUGULAR VEIN
In the normal adult horse and cow, the jugular vein will be distended with blood some 5–8 cm above the level of the base of the heart when the animal is standing with its head in a normal, nonfeeding, alert position. There is a rapid but minor fall in the level of jugular distension associated with the fall of blood into the ventricle during the period of rapid filling during ventricular diastole followed by a slower rise in the level of jugular filling to its original point. Superimposed on this, and immediately preceding the fall, is a small wave or retrograde distension associated with atrial contraction ('a' wave) and a second smaller retrograde
wave (‘c’ wave) associated with bulging of the atrial ventricular valves into the atrium during ventricular systole. These pulsations can be observed in most horses and cattle by careful observation of the jugular vein at its entrance into the thorax and can be timed in conjunction with auscultation of the heart.

Observation of the presence or absence of the atrial ‘a’ wave is an aid in the clinical differentiation of first- and second-degree heart block. Cannon atrial waves occur periodically in complete heart block when atrial contractions occur against a closed atrioventricular valve. An accentuated ‘c’ wave occurs with tricuspid valve insufficiency.

MEASUREMENT OF JUGULAR VENOUS PRESSURE

The jugular veins are symmetrically distended in chronic (congestive) right-sided heart failure. This distension is accompanied by an increased jugular venous pressure that can be subjectively assessed by palpation or objectively determined by measuring jugular venous pressure.

This underutilized technique can be easily and rapidly performed. The equipment required is a 14-16-gauge needle attached to a three-way stopcock. A 20 mL syringe containing heparinized 0.9% NaCl is attached directly opposite the needle, and a flexible rigid wall fluid administration line is attached to the remaining port on the three-way stopcock. The stopcock is turned so that the needle is in the off position, the needle is threaded down the jugular vein towards the heart, the syringe is pushed to fill the heart, the syringe is turned so that the syringe is in the off position. Blood will flow into the flexible tube and the vertical distance (in cm) between the top of the column of 0.9% NaCl supported by the jugular venous pressure and the point of the shoulder (scapulohumeral joint), which approximates the position of the right atrium, is a direct measure of jugular venous pressure.

REFERENCES

EXERCISE TOLERANCE

Dyspnea, fatigue and a prolonged elevation in heart rate following exercise are signs suggestive of cardiac insufficiency. Frequently, animals with suspect cardiac disease are exercised in an attempt to elicit these signs and to get an estimate of exercise tolerance. In most practice situations the assessment of exercise tolerance is subjective. There is obviously a considerable difference in the amount of exercise that a beef bull and a trained racehorse can tolerate under normal conditions, and the amount of exercise given to any one animal is determined by the clinician’s judgment. The rate of fall in heart rate following exercise and the time required to reach resting levels depend upon the severity of the exercise, even in fit horses. Heart rate falls rapidly over the first minute and then more slowly over the ensuing 10-15-minute period.

More objective tests have been developed for the horse, which include evaluation by means of telemetry from horses timed over a measured distance on race tracks or the use of a treadmill to provide a defined amount of exercise. The amount and intensity of exercise can be varied by the speed and incline of the treadmill and by the duration of the exercise period. The treadmill allows the recording of a variety of cardiorespiratory measurements in the exercising horse and can be used for evaluating the significance of cardiopulmonary disease and for establishing the cause of poor racing performance.

There are many noncardiac causes of exercise intolerance and, in a report on the evaluation of 275 horses, 84% were found to have more than one problem leading to poor athletic performance.

Criteria for cardiovascular performance in endurance rides are described and the rapidity of heart rate decline following completion of each section of the ride can be used for field assessment of this function.

ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) provides a record and measure of the time varying potential difference that occurs over the surface of the body as the result of electrical activity within the heart. This is associated with depolarization and repolarization of the myocardium. At any one instant during depolarization and repolarization there are generally several fronts of electrical activity within the heart. However, at the body surface the potential difference is generally the sum of this activity and at any one instant the electrical activity in the heart registers as a single dipole vector that has polarity, magnitude and direction.

The polarity is determined by the charge on the surface of the cells while the magnitude and direction is determined by the mass of muscle being depolarized or repolarized and the sum of the instantaneous vectors. Thus a wave of depolarization or repolarization over a muscle mass such as the atria or the ventricles is presented at the body surface as a sequence of instantaneous vectors with changing magnitude and direction.

THE ELECTROCARDIOGRAPH

The electrocardiograph is used to detect these characters. In simple terms it can be considered as a voltmeter consisting of two input terminals, an amplifier to allow the recording of low input signals and a galvanometer with an attached recording device such as a heated stylus on heat sensitive paper or an ink pen or ink squirter. When a potential difference exists across the input terminals (electrodes), current flows through the coils of the electromagnet suspended between the poles of the permanent magnet to cause a deflection of the recording pen. The electrocardiograph can therefore detect the polarity of the cardiac electrical vectors and by calibration of the machine and appropriate placement of electrodes on the body surface it can detect their magnitude and direction.

Calibration of most electrocardiographs is such that an input of 1 mV produces a 1 cm deflection of the recording pen. Recording speeds are generally 25 or 50 mm/s. In recording an ECG, certain standard electrode positions are used for recording.

- A lead is the recording or circuit between two recording points. Depending upon the wiring within the electrocardiograph the same potential difference across a lead could result in an upward or downward deflection of the recording pen.
- In order to allow standard recording and comparison between recordings the polarity of the electrodes for standard leads has been established by convention and the leads are always recorded at these polarities.
- The electrodes of a lead are commonly called positive or negative.
- A positive electrode in a lead is one that, when electrically positive relative to the other, due to a potential difference between them, yields an upward or positive deflection of the recording pen.
DEPOLARIZATION AND REPOLARIZATION

In the normal heart, depolarization and repolarization of the myocardium occurs in a definite pattern and sequence and the electrocardiography can be used to measure and time these events. Thus discharge of the sinoatrial node results in a wave of depolarization over the atria to produce a P wave in the ECG. The delay in conduction at the AV node is registered by no electrical activity at the body surface and an isoelectric P–R interval on the ECG (isoelectric means zero voltage difference between the two leads). Depolarization of the ventricles occurs with several sequential fronts to produce the QRS complex, which is followed by another isoelectric period before repolarization represented by the T wave.

In dogs, cats and humans the electrocardiogram can be used to assess the cardiac rhythm and the size of the cardiac chambers. However, the order of ventricular activation in horses, cattle, sheep and swine differs from that of humans and dogs in that ventricular depolarization is represented by only two fronts of activity. Depolarization of a large proportion of the myocardial mass in large animals is not recognized by the surface electrocardiogram because the Purkinje fibers penetrate much more deeply in these species and depolarization occurs over multiple minor fronts that tend to cancel out, rather than over a large single front as in dogs. For this reason, the detection of chamber enlargement by vector analysis of the electrocardiogram is, in general, not possible in large animals. Consequently, electrocardiography is confined to a simple base–apex lead system to examine for conduction disturbances and arrhythmias, which are detected by measurement of the various waveforms and intervals in the ECG that represent depolarization and repolarization in the heart, and by observation of their absence or abnormality.

LEAD SYSTEMS

The base–apex lead system provides the best method for electrocardiography in large animals, with the only exception being fetal electrocardiography. All other lead systems are clinically superfluous or inferior, or have only a research application.

Traditional lead systems are based on Einthoven’s triangle as used in humans, and the standard bipolar limb leads (I, II and III) and the augmented unipolar limb leads (aVR, aVL, aVF) are commonly used in conjunction with an exploring unipolar chest lead. Variations in the position of the feet may produce changes in ECG waveforms with this lead system and recordings should be taken with the animal standing square or with the left front foot set slightly in advance of the right front foot. This lead system is quite satisfactory for the detection of conduction disturbances and arrhythmic heart disease but is subject to movement artefact. There are, however, deficiencies associated with its use for the detection of changes in the magnitude and direction of electrical vectors in the heart of large animals. Nevertheless, traditional lead systems have been used extensively for this purpose.

Vector-based lead systems. There have been several studies to determine if it is possible to detect changes in cardiac chamber size in large animals. Many of these have examined alternative lead systems, recognizing that the standard limb leads are not particularly suited for detection of vector changes associated with changes in chamber dimensions. The standard limb leads are primarily influenced by vectors in the frontal plane (longitudinal and transverse) whereas early and late forces in the myocardium are significantly directed in the vertical direction. Furthermore, the heart is not electrically equidistant from the electrodes of each lead and distortion of recorded vector loops can result. A partial correction of these deficiencies can be made by recording a lead using an exploring electrode at the V10 position over the dorsal spinous processes in addition to the standard limb leads. However, for proper representation of the vector changes associated with electrical activity within the heart, completely different electrode placement is required. A number of systems have been proposed. The electrode placement varies and is quite complicated but electrocardiographic studies using these methods are available for horses, cattle, pigs and sheep. In general, a three lead system consisting of leads I, aVF and V10 provides semiorthogonal axes suitable for three-dimensional reconstruction of depolarization and repolarization.

The base–apex lead system is most commonly used as it records the major electrical forces in the heart of large animals with consistently clear and large-amplitude waveforms. Animal movement also has minimal effect on the quality of the ECG. The most commonly used bipolar lead placement in horses and cattle consists of two electrodes, one positive and one negative, in a format called the base–apex lead. The positive electrode of lead I (left arm) is attached to the skin of the left thorax at the fifth intercostal space immediately caudal to the olecranon, and the negative electrode (right arm) is placed on the jugular furrow in the caudal third of the right neck. This is the most common lead placement, although some investigators place the negative electrode on the left side of the neck instead of the right side. With sheep, where wool interferes with placement on the neck, the negative electrode can be placed on the midline of the poll. When using the base–apex lead system, the ground electrode is placed remote from the heart, and the location of the ground is not important. The electrodes are usually placed using alligator clips and a 70% isopropyl alcohol or gel contact, although disposable human stick-on type electrodes can be used in horses after clipping of the skin and cleaning with alcohol before application of the gel. In order to ensure good adherence to the skin, the skin should be shaved and cleaned with alcohol prior to the application of the gel. The ECG is recorded with the animal in a standing position with minimal restraint. Normal values for cattle, horses, and pigs are summarized in Table 8.1.

FETAL ELECTROCARDIOGRAPHY

The fetal ECG may be recorded, and can be of value in determining if the fetus is alive, the presence of a singleton or twins, and as a monitor for fetal distress during difficult or prolonged parturition. A modified bipolar lead system is required, with the RA electrode being placed on the right ventral abdomen and the LA electrode below placed on the ventral midline in front of the umbilical. The ground lead can be situated anywhere. The bipolar lead should be recorded using increased sensitivity with meticulous attention to obtaining the best electrical connection to the skin. The animal needs to be electrically isolated (standing on a rubber mat) and muscular activity must be minimized.

Values are obtained from 600 healthy Holstein–Friesian female cattle aged 1 or more years (Zakukhan A et al. Vet Arch 2004; 74:351), 17 healthy male and female horses aged 6 months to 8 years (P Constable, personal communication) and 467 healthy sows (Takemura N et al. Jpn Vet Med Assoc 1988; 41:398).
Fetal electrocardiography has been used in cattle to monitor fetal viability, but the fetal ECG signal is very weak and suffers from interference from the maternal ECG, the electromyogram and motion artifacts caused by gastrointestinal movement. For these reasons, the position of the bipolar recording leads on the abdomen should be moved to provide the optimal recording site for each cow. Digital processing of the fetal ECG signal can assist in detection of fetal heart rate, at more than 157 days of gestation. Fetal heart rates for calves are measured as an indicant of hypoxia and early growth of the foal. The mean electrical axis is constant between 140 beats/min from 150 days before term to 110 beats/min at 157 days before term.

**Heart rate variability** has received recent interest as a research method to evaluate the relative contributions of sympathetic and parasympathetic tone to the cardiovascular system. Heart rate variability has been assessed in cattle using time domain and frequency domain procedures.

**SERUM CARDIAC TROPONIN I CONCENTRATION**

The serum concentration of cardiac troponin I provides an excellent cardiac biomarker in large animals, providing a sensitive and persistent indicator of cardiac injury. Troponin I, T and C are components of the troponymiosin–troponin complex in cardiac and skeletal muscle, with cardiac troponin I and T having different amino-acid sequences at the N-terminal end compared to skeletal muscle troponin I and T. This means that an immunoassay directed at the N-terminal end will be able to differentiate between cardiac and skeletal muscle isoforms and therefore the site of injury. Myocardial tissue from horses, cattle, sheep and pigs has high reactivity for cardiac troponin I when tested using a human immunoassay, and this reactivity is selective for the myocardium, being more than 1000-fold higher in cardiac tissue than in skeletal muscle. Cardiac troponin I has greater myocardial selectivity than cardiac troponin T, and is therefore preferred as a biomarker of cardiac injury. Serum activities of cardiac isoenzymes of creatine kinase (creatine kinase isoenzyme MB (CK-MB)) and lactate dehydrogenase (isoenzymes 1 and 2) have been used in the past to detect traces of cardiac disease in horses. However, only 1.5% of the total CK activity in the equine heart is attributable to CK-MB (compared to 20% in the human heart); therefore CK-MB is an insensitive indicator of cardiac disease in the horse. Isoenzymes of lactate dehydrogenase suffer from a similar lack of specificity for cardiac disease. Cardiac troponin I is the preferred biomarker for detecting and quantifying cardiac disease in animals, and healthy horses have cardiac troponin I concentrations below 0.11 ng/mL using the human immunoassay. Healthy neonatal foals have cardiac troponin I concentrations of less than 0.49 ng/mL. Healthy cattle have cardiac troponin I concentrations below 0.04 ng/mL.

**PHONOCARDIOGRAPHY**

Phonocardiography allows the recording and measurement of heart sounds. A special microphone is placed directly over the various areas of the thorax used for heart auscultation and the heart sounds are recorded graphically on moving paper or on an oscilloscope. Prior to recording, the heart sounds are usually passed through high-pass, low-pass or band-pass filters to allow better discrimination of the individual sounds and to allow a crude frequency examination. Phono-
Cardiograms are usually recorded in conjunction with an electrocardiogram and chamber pressure measurements, which permits timing of their occurrence in relationship to the electrical activity within the heart.

Phonocardiograms can provide considerable information on heart sounds additional to that acquired by stethoscopic examination. In the horse, up to 11 sound events can be detected in each cardiac cycle and figures of the occurrence and duration of normal heart sounds in large animals are available. In conjunction with an electrocardiogram, the phonocardiogram can be used to measure systolic time intervals, which may be altered in congenital and acquired cardiovascular abnormalities.

Phonocardiograms have been infrequently used for the characterization and timing of murmurs in animals with cardiovascular disease, especially at fast heart rates where simple stethoscopic examination may not allow this. However, phonocardiography has been rarely used as a clinical diagnostic tool, and the widespread availability of echocardiographs makes the clinical application of phonocardiography less likely in the future.

CARDIAC OUTPUT
There are several techniques available for the measurement of cardiac output but the one almost universally applied in large animals is the indicator dilution technique using thermodilution (injection of iced 5% dextrose) or indicator dyes such as Evans blue, indocyanine green or lithium chloride. With dye dilution, an exact amount of dye is injected into the jugular vein or pulmonary artery via a catheter and the serial collection of blood samples is performed from a suitable proximally located artery that has been catheterized. Cardiac output is most commonly measured using thermodilution but can also be calculated from a dye dilution curve by determining the mean concentration of the dye and the time taken for one circulation through the heart. Automated cardiodensitometers are also available for this estimation. Cardiac output is expressed as liters per minute and is usually corrected to cardiac index on the basis of weight or body surface area.

Most domestic animals have a cardiac index of 100 (mL/kg body weight (BW))/min at rest. The cardiac index for horses, sheep and cattle at rest has been determined as 86 ± 13, 131 ± 39 and 113 ± 11 (mL/kg)/min, respectively. Stroke volume can also be calculated from the measured cardiac output and simultaneously determined heart rate, whereby stroke volume = cardiac output/heart rate. In general the normal variation between animals in indexes of cardiac output is too great to allow it to be used as a diagnostic measure in individual animals suspected to have cardiac disease. Measures of cardiac output are used in experimental studies, where the effects of certain procedures can be followed within the same animal. Indicator dilution curves using dyes or thermodilution methodology can be used to detect the presence of intracardiac defects such as septal defects and to quantify their significance.

Doppler echocardiography can be used to estimate cardiac output and gives values equivalent to those obtained by thermodilution techniques.

MEASUREMENT OF ARTERIAL BLOOD PRESSURE
Blood pressure may be determined directly by arterial puncture and pressure measurement but this is impractical in clinical cases. The development of simple methods for the indirect determination of arterial blood pressure has proved difficult in large animals because of the paucity of suitably located arteries where a pressure cuff can be applied and because there are problems in detecting pulse return by simple auscultatory or palpatory methods.

In the horse a simple and relatively inexpensive method uses oscillometric sphygmonanometry to detect arterial pulsations and therefore simultaneously determine heart rate and mean arterial pressure. For adult horses, the optimal cuff width for the oscillometric method is approximately 20–35% of the tail circumference, when the cuff is applied snuggly to the base of the tail and the ventral coccygeal artery pressure is monitored. The mean tail circumference of an adult horse is 22 cm, therefore the optimal cuff width for horses is 5–8 cm for oscillometric pressure measurement. Because the oscillometric units were designed for use in humans, the software programs often have difficulty in measuring arterial pressure when the heart rate is less than 40 beats/min and when arrhythmias or arterial hypotension are present, which minimizes the clinical utility of these units in trained or sick horses. The units are also susceptible to motion of the tail and it is therefore preferable to keep the tail still during recording. Other methods of indirect pressure measurement in the horse (modified auscultatory technique, ultrasonic Doppler methodology) appear less accurate than the oscillometric sphygmonanometry. Moreover, oscillometric techniques offer the advantage of providing systolic, diastolic and mean arterial blood pressures, whereas other indirect methods do not provide mean arterial pressure.

Systolic and diastolic blood pressure of a large series of trained Thoroughbred horses were 112 ± 16 mmHg (14.9 ± 2.1 kPa) and 77 ± 14 mmHg (10.2 ± 1.9 kPa) respectively. Equivalent values have been recorded in other breeds. These values are coccygeal uncorrected values and can be corrected to the correct reference level (scapulohumeral joint, which is equivalent to the right atrium) by adding 0.7 mmHg (0.09 kPa) for every centimeter in height between the scapulohumeral joint and the tail if the coccygeal artery was the recording site for indirect pressure measurement. Posture of the horse is important, as lowering the head significantly lowers systolic, diastolic and pulse pressure.

Hypertension has been found in association with epistaxis, lami nitis in horses and painful fractures of the distal bones of the limb. Systolic blood pressure is often also elevated in obstruction of the large intestine in horses. Blood pressure measurements are of value in the assessment of the degree of shock and possibly may prove of value in the differential diagnosis of conditions such as acute salmonellosis and in assessing the prognosis of colic. Mean arterial pressure is considered the true driving pressure for blood flow and organ perfusion, therefore determination of mean arterial pressure provides one index of perfusion. However, it is important to recognize that mean arterial pressure is poorly correlated with cardiac output.

Blood pressure readings can be obtained by equivalent techniques from the tails of cattle. However, because of anatomical differences these do not always correlate well with true blood pressure. Pressures have been observed to be 100–140 mmHg (13.3–18.6 kPa) systolic and 50–85 mmHg (6.7–11.3 kPa) diastolic.

ECHOCARDIOGRAPHY

Echocardiography has provided a relatively simple and noninvasive method for the examination of the heart that can give considerable information on its function. In echocardiography, high-frequency sound waves are pulsed through tissues at known velocities. When the sound waves encounter an acoustic tissue interface, echoes are reflected back to a transducer and recorded in a number of different modalities. The modalities have become increasingly sophisticated and they have largely replaced traditional invasive evaluations of cardiac function such as cardiac catheterization. The newer technologies are expensive and are currently limited to teaching hospitals and referral clinics.

Echocardiography will allow the measurement of cardiac chamber size, wall thickness, global and regional wall movement and valve structure and function.1-3 Functional indices can be calculated that will allow the determination of the presence of hypertrophy or dilatation of areas of the heart and the percentage of wall thickening.4 The fractional shortening of the left ventricle can be used as a sensitive index of left ventricular contraction. Quantitative studies are available for the horse,5-11 sheep,12 pigs13 and cattle.14-16 The measurement of the ratio of cardiopulmonary blood volume to stroke volume, determined from a radiocardiogram following the injection of technetium-99m pertechnetate, has proved a more sensitive test for cardiac insufficiency in horses than measurements of cardiac output.17 Measurements of cardiac and individual chamber dimensions, vessel diameters and flow rates can be used to assess normality, indexes of contractility and effects of cardiac lesions on cardiac response and function.5,18-21 They can also be used to predict the type of lesion likely to result in these changes.19

Valvular defects and endocarditis may be diagnosed by imaging abnormal valve motion, incompetent valve orifices or vegetative masses associated with the valves22 and tumor masses in the heart can be detected.23 Similarly, the severity of valvular regurgitation can be quantified.24 Echocardiography can be of considerable value in the diagnosis of congenital cardiovascular defects and the injection of echogenic materials such as microbubble-laden saline may aid in the detection of shunts.2-5,19 Echocardiography can also be used to determine the presence and extent of pleural and pericardial effusion. In the examination of the vascular system, ultrasound is capable of the early detection of iliac thrombosis in horses and is more sensitive than manual palpation per rectum.25 There is a long-held belief that horses with a large heart relative to their body size have greater athletic capacity.25 An accurate and noninvasive method for determining heart weight therefore has potential utility as one method for predicting racing success. Echocardiography provides a useful estimate of heart weight that may compliment electrocardiographically determined heart score (calculated from the QRS duration) in the prediction of athletic performance. The thickness of the interventricular septum in diastole provides an accurate prediction of heart weight,26 the predictive accuracy was such that echocardiography using this measurement has utility as an index of subsequent athletic performance27 and has been used in North America, Europe and Australia in such a manner.

CARDIAC CATHETERIZATION

The measurement of pressure within the various chambers of the heart and in the inflow and outflow vessels can provide diagnostic information in both acquired and congenital heart disease in large animals. Generally, pressure is determined by means of fluid-filled catheters introduced into these areas and connected to an external pressure transducer. These systems are generally satisfactory for the measurement of pressure and the detection of changes with abnormality. However, because of their transmission characteristics, they are less suitable for the precise timing of pressure events, and high-fidelity catheter tip manometers should be used for this purpose.

Catheterization of the right side of the heart is a comparatively simple procedure in large animals but is not without risk to the animal. Catheterization is done in the standing position, and descriptions are available for horses,2 and cattle.3-7 Flow-directed catheters are used and can be introduced through a needle inserted into the jugular vein. Balloon-tipped catheters aid the flow of the catheter into the pulmonary artery. Catheterization of the left side of the heart is more complicated and less commonly performed. Left heart catheterization is usually performed under general anesthesia and requires the use of a stiff catheter that is introduced into the carotid or femoral artery by surgical methods and subsequently manipulated to the left ventricle.

The systematic determination of the pressure within each area of the heart and in the inflow and outflow vessels can allow a determination of the type of abnormality that is present. Valvular stenosis or incompetence is associated with abnormal pressure differences across the affected valve during systole or diastole. Cardiac hypertrophy is generally accompanied by an increase in pressure during systole of the affected chamber. With high-fidelity equipment, pressure waveforms can also have diagnostic value.

The right atrium is usually used as the reference point for pressure comparison and is arbitrarily assigned a reference pressure of zero when recording using a fluid-filled catheter system. The scapulo-humeral joint (point of the shoulder) is taken as the anatomical equivalent reference height in the standing animal.4 A simultaneously recorded base–apex electrocardiogram assists in interpretation of the pressure tracings. Numerous publications have reported cardiovascular values for conscious awake horses, adult cattle and calves, and representative values are presented in Table 8.2.

During catheterization blood may be withdrawn through the catheter and subjected to blood gas analysis. In right-sided catheterization an increase in
within the right atrium and ventricle)

The normal maximum increase in venous pulmonary artery can be diagnostic for to an atrial septal defect, a ventricular septal defect or a patent ductus arteriosus.

Oxygen content between the right heart atrium to right ventricle and 0.5 mL blood flow and variability in sampling site gas analysis indicate the presence of a chambers and pulmonary artery in septal defect or a patent ductus arteriosus.

Oxygen content (due to streaming of magnitude of the shunt by calculating the with a left-to-right shunt, the pulmonary

in healthy individuals, with the exception left-to-right to shunt; sequential blood

animals with an atrial septal defect), $P_{O_2}$ in animals with a patent ductus arteriosus, $P_{O_2}$ 0.8 In animals

therefore approximate 1.0. In animals

such a large shunt into the right ventricle

was confirmed at necropsy.

Shunts can also be demonstrated by dye or thermodilution techniques, but these are much more complicated to analyze than blood gas analysis of sequential blood samples obtained from a fluid-filled catheter during a pullback from the pulmonary artery through the right ventricle into the right atrium.

Echocardiography can provide information that, while different, may be of equivalent diagnostic value to that obtained by cardiac catheterization and, because it is noninvasive and technically a much easier procedure, echocardiography has largely supplanted cardiac catheterization in the examination of cardiac disease in large animals.

**RADIOGRAPHIC AND ANGIOCARDIOGRAPHIC EXAMINATION**

Because of the size of horses and cattle these methods of examination are largely confined to neonates of these species except in teaching hospitals. Angiocardiography can be a diagnostic method of examination in congenital cardiac defects where the passage of contrast media through abnormal routes can be detected.

**Arrhythmias (dysrhythmias)**

Variations in cardiac rate and rhythm include tachycardia (increased rate), bradycardia (decreased rate), arrhythmia or dysrhythmia (irregularity in rate and rhythm) and gallop rhythms. The rate and rhythm of the heart is influenced primarily by the integrity of the pacemaker, the conducting system and the myocardium, and also by the influence of the autonomic nervous system. Variation in the rate and rhythm can occur in normal animals due to strong or varying autonomic influence but can also be a reflection of primary myocardial disease. Other factors such as acid–base and electrolyte imbalance can influence rate and rhythm. These factors must be taken into consideration in the assessment of apparent abnormalities detected on clinical examination of the cardiovascular system.

The majority of arrhythmias and conduction disturbances can be detected on clinical examination. However, some may be unsuspected on clinical examination and be found only on electrocardiographic examination. The occurrence of conduction and myocardial disturbances is probably more common than generally recognized, because an electrocardiogram is usually only taken from animals in which there have been prior clinical indications of conduction abnormalities. Because of the importance of electrocardiography in the diagnosis of arrhythmias the salient electrocardiographic findings are given in the sections below.

The common conduction disturbances and arrhythmias in large animals are listed in Table 8.4. A large scale cross sectional study of 952 healthy dairy cattle aged 1 or more years produced the following prevalence of arrhythmias: sinus arrhythmia, 8.5%; first-degree atrioventricular block, 1.6%; ventricular premature complexes, 0.6%; atrial premature complexes, 0.4%; sinus bradycardia, 0.2% and ventricular escape beats, 0.1%. Atrial fibrillation was not observed in healthy cattle in this study.

The treatment of arrhythmic heart disease generally relies on the treatment of the underlying clinical condition causing the problem. This may vary from electrolyte and acid–base disturbance and toxicities to primary myocardial disease resulting from myocarditis, myocardial ischemia and changes resulting from heart failure or myopathies resulting from nutritional deficiency. These are detailed in later sections in this text. Racing and work horses should be rested for periods up to 3 months following evidence of myocardial disease. Frequently a course of corticosteroids, or a nonsteroidal anti-inflammatory drug (NSAID) such as flunixin meglumine, is given to attempt to reduce the severity of myocarditis if it is not contraindicated by the initiating cause. Specific antiarrhythmic therapy may be applied in certain conditions and is detailed below.

It is important to be able to recognize those forms of arrhythmia that are not indicative of pathological heart disease but are normal physiological variations. These occur commonly in the horse and most can be differentiated on physical examination. It is also important to understand the difference between a premature beat or contraction and a premature complex. A beat or contraction is a mechanical event that can be clinically detected by auscultation, palpation of an artery or visual examination of the jugular venous pulse, or recorded by pressure measurements. A complex is an electrical event that is detected by an electrocardiograph. A beat is always associated with a complex; however, a complex can be unaccompanied by a beat, particularly in electromechanical dissociation. The terms beat or contraction should therefore be used to describe an arrhythmia that is detected by auscultation, palpation or recording of the arterial pulse, whereas the term complex should be used when the arrhythmia is detected electrocardiographically.

**REFERENCE**

**SINUSS TACHYCARDIA, SINUS BRADYCARDIA AND PHYSIOLOGICAL DYSRHYTHMIAS**

The heart rate results from the discharge of impulses from the sinoatrial node, which has its own intrinsic rate of discharge but which is also modified by external influences, particularly the vagus nerve.

**SINUSS TACHYCARDIA**

The term sinus tachycardia or simply tachycardia is used to describe an increase in heart rate caused by detectable influences such as pain, excitement, exercise, hyperthermia, a fall in arterial blood pressure or the administration of adrenergic drugs. The heart rate returns to normal when the influence is removed or relieved.

It needs to be stated that sinus tachycardia indicates an increase in heart rate that is initiated by the sinoatrial node in the right atrium (hence the sinus modifier). This means that the term sinus tachycardia should be reserved for use when electrocardiography has been performed and the sinus node has been determined to be the dominant pacemaker. For comparison, the term tachycardia should be used when an increased heart rate is detected by auscultation or palpation of the pulse and the origin of the pacemaker has not been determined. In resting horses and cattle that are used to being handled heart rates are not usually elevated above 48 and 80 beats/min respectively and rates above this are usually classified as tachycardia (Figure 8.1). In the cow and horse it is rare for the causes of sinus tachycardia to elevate the heart rate above 120 beats/min in the resting animal, and at heart rates above this an intrinsic pathological tachycardia should be sought.
SINUS BRADYCARDIA

Sinus bradycardia or simple bradycardia is used to describe a decrease in heart rate due to a decreased rate of discharge from the sinoatrial node. Sinus bradycardia is most commonly associated with highly trained, fit animals and can be differentiated from the pathological bradycardias by its abolition by exercise or the administration of atropine. Obviously sinus bradycardia, like sinus tachycardia, requires electrocardiographic confirmation that the sinus node is the dominant pacemaker.

Bradyard may also occur in association with an increase in arterial blood pressure, space-occupying lesions of the cranium and increased intracranial pressure, pituitary abscess, hyperkalemia (Figure 8.1) hyperthermia and hypoglycemia and following the administration of alpha-2-adrenergic agonists such as xylazine or detomidine. Bradyardia is sometimes associated with vagus indigestion and diaphragmatic hernia in cattle and also occurs in cattle deprived of food. Bradyardia has also been reported in cattle with bovine spongiform encephalopathy, although this probably reflects inappetence rather than damage to the vagal nucleus in the brain stem; the latter would be expected to increase, rather than decrease, heart rate. Bradyardia can be induced in young ruminants by forceful elevation of the tail. Sinus arrhythmia is usually present in animals with sinus bradycardia.

The resting heart rate seldom falls below 22 beats/min in adult horses and 44 beats/min in adult cattle. Rates below this are suggestive of pathological bradycardias, and hypothermia, hypothyroidism or an intrinsic cardiac problem should be suspected. However, a general rule is that resting heart rates are inversely proportional to body weight, and large, fit horses and cattle have apparently low heart rates.

PHYSIOLOGICAL ARRHYTHMIAS

There are several dysrhythmias that can occur in the absence of heart disease and that appear to result from excess vagal tone. These occur especially in the horse and include:

- Sinus arrhythmia
- Wandering pacemaker
- Sinoatrial block
- First-degree and second-degree atrioventricular block.

These physiological arrhythmias occur in animals at rest and can frequently be induced by the application of a nose twitch in horses or by forceful elevation of the tail in young ruminants. There is some debate as to the significance of these arrhythmias in animals but it is generally believed that if they are abolished by exercise or excitement and if there is no evidence of cardiac insufficiency they are not of pathological significance and do not require further investigation.

Perinodal myocardial fibrosis and microvascular abnormality have been reported in horses with sinoatrial and atrioventricular block, and considered as the excitatory cause. However, because myocardial fibrosis is common in horses, being present in 79% of horse hearts examined at random, it remains likely that these arrhythmias are physiological in horses. All animals with evidence of arrhythmic heart disease should be examined following exercise, as should any animal in which cardiac disease is suspected.

The occurrence of cardiac irregularities following exercise is highly indicative of serious cardiac disease.

A high frequency of arrhythmia has been recorded in newborn foals immediately following birth. Of 50 foals had some form of arrhythmia: atrial premature complexes were recorded in 30 foals, atrial fibrillation in 15 foals and ventricular premature complexes in 10 foals. Other arrhythmias were recorded with less frequency. It was concluded that the arrhythmias resulted from transient

Fig. 8.1 Base-apex electrocardiograms of large animals with normal sinus rhythm (panels A & B), supraventricular arrhythmias (panels C, D, E, F, G, & H), hyperkalemia (panels H & I) or ventricular arrhythmias (panels J, K, & L). All electrocardiograms were recorded at 25 mm/sec and 10 mm = 1 mV.
All electrocardiograms were recorded at premature complexes, ventricular premature complexes and atrial fibrillation (in a 7-day-old calf with diarrhea and severe acidemia (jugular venous blood pH = 6.90)).

Sinus arrhythmia is a normal physiological variant that occurs at slow resting heart rates and is associated with variation in the rate of discharge from the sinoatrial node associated with variation in the configuration of the P wave. It is commonly correlated with respiration so that the discharge rate and heart rate increase during inspiration and decrease during expiration. In the horse, sinus arrhythmia unassociated with respiration also occurs. In the majority of large animals, sinus arrhythmia is much less overt than in the dog and generally it is not detected except on very careful clinical examination or examination of the electrocardiogram. Sinus arrhythmia is more clinically obvious in tame sheep and goats and in the young of all species and is correlated with respiration. It is abolished by exercise or by the administration of atropine.

In the electrocardiogram sinus arrhythmia is detected by variations in the P–P intervals (greater than 10% of the mean heart rate) with or without variation in the P–R interval and is frequently associated with a wandering pacemaker. This is associated with differences in the site of discharge from the sinoatrial node with subsequent minor variations in the vector of atrial depolarization with subsequent minor variations in the configuration of the P wave. In the horse there may be an abrupt change in the contour of the P wave so that the normal biphasic positive P wave in lead II, for example, changes to one with an initial negative deflection. There may or may not be a change in P–R interval. This is not pathological and is present in as many as 30% of normal horses at rest. If sinus arrhythmia is not abolished by exercise it is considered pathological. Sinus arrhythmia may be induced in the early stages of hypercalcemia during treatment for milk fever in cattle.

**SINOATRIAL BLOCK**

In sinoatrial block the sinoatrial node fails to discharge or its impulse is not transmitted over the atrial myocardium. It is associated with the complete absence of heart sounds, of jugular atrial wave and of an arterial pulse for one beat period. The underlying rhythm is regular unless sinus arrhythmia is present. In the electrocardiogram there is complete absence of the P, QRS and T complex for one beat. The distance between the preblock and postblock P waves is twice the normal P–P interval or sometimes slightly shorter. This arrhythmia is not uncommon in fit racing horses at rest and can be induced in horses and cattle by procedures that increase vagal tone. Provided it does not persist during and following exercise it is considered as a physiological variant of normal rhythm.

**ARRHYTHMIAS WITH NORMAL HEART RATES OR BRADYCARDIA**

**SINUS ARRHYTHMIA**

Sinus arrhythmia is a normal physiological arrhythmia that occurs at slow resting heart rates and is associated with variation in the rate of discharge from the sinoatrial node associated with variation in the intensity of vagal stimulation.

**ATRIOVENTRICULAR BLOCK**

Atioventricular block is divided into three categories depending upon the...
degree of interference with conduction at the atrioventricular node.

First-degree atrioventricular block
This is an electrocardiographic diagnosis and cannot be detected clinically. It occurs when conduction is delayed at the atrioventricular node. The P–R interval is prolonged beyond normal limits (conventionally > 400 ms in the horse) and the condition may be transient because of waxing and waning vagal tone. First-degree atrioventricular block is generally considered to have little significance.

Second-degree atrioventricular block
Also called partial heart block, this occurs when there is periodic interference with conduction at the atrioventricular node so that some atrial contractions are not followed by ventricular contraction (Figure 8.1). This may occur apparently at random or occur in a regular pattern, for example at every third or fourth beat. At the blocked beat there is complete absence of the first and second heart sounds and no palpable pulse. The underlying rhythm is still sinus in origin and is thus regular. In horses the presence of a fourth heart sound can be a valuable aid to diagnosis as with careful auscultation it can be heard during the block period in the manner of du LUBB DUPP du ..., du LUBB DUPP. This is diagnostic for this condition. An atrial jugular impulse can also be detected during the block period. The intensity of the first sound in the immediate postblock beat is usually intensified.

The electrocardiogram shows the presence of a P wave but complete absence of the subsequent QRS and T waves at the blocked beat. There may be variations in the P–R intervals preceding and following the block. With Mobitz type 1 (Wenkebach) second degree atrioventricular block there is a gradual increase in the PQ interval up to the point of the blocked conduction. With Mobitz type 2 block the PQ interval remains unchanged. In most species, Mobitz type 1 is a normal physiological response reflecting changes in vagal tone, whereas Mobitz type 2 always indicates the presence of organic heart disease such as myocarditis. However, many second-degree atrioventricular blocks in horses do not fit these two categories and the PQ interval increases until the immediate preblock complex in which it may be decreased. The clinical significance of these variations in the horse has not been established.

Second-degree atrioventricular block is extremely common in horses and occurs as a normal physiological variation due to variations in vagal tone. The application of a twitch to the upper lip of a horse will frequently slow the heart rate and allow the expression of second-degree heart block. It is more common in Thoroughbreds and Standardbreds than in heavy horses and may be detected in approximately 20% of racehorses. Frequency is highest when they are examined in quiet surroundings at rest, at night or early in the morning. Second degree atrioventricular block can be abolished by exercise or the administration of atropine.

Second-degree atrioventricular block can be associated with myocarditis in the horse and its presence has been associated with decreased racing performance by some clinicians. Second-degree atrioventricular block at fast heart rates has also been associated with the syndrome of duodenitis–proximal jejunitis in horses and was correlated with high serum bicarbonate concentrations in this condition. Atrioventricular conduction disturbances can be associated with electrolyte imbalance in all species, overdosing with calcium salts, digoxin toxicity, cardiomyopathy and myocarditis associated with nutritional and infectious disease.

Methods for the clinical differentiation of physiological (Mobitz type 1) versus pathological (Mobitz type 2) second-degree heart block in the horse have not been established. However, the persistence of the arrhythmia at heart rates above resting normal values should be considered to be abnormal. In all other species the presence of Mobitz type 2 atrioventricular block should probably be considered as an indication of myocardial disease.

There is usually no necessity to treat this arrhythmia specifically and treatment is generally directed at the underlying cause. In cases where the block is frequent and syncopal episodes are likely, atropine may give some alleviation of the frequency of the block; however, this is only short-term therapy. Second-degree heart block may progress to third degree (complete) heart block.

Third-degree or complete heart block
This occurs rarely in large animals, or perhaps is seen only infrequently because it is almost invariably fatal. In complete heart block there is no conduction at the atrioventricular node. The ventricle establishes a pacemaker in the nodal or conducting system and the atria and ventricles beat independently. The ventricular rate is regular but very slow. Bradycardia is the prominent feature and it is unresponsive to exercise or atropine. Atrial contractions are much faster than the ventricle. Atrial contraction sounds are rarely heard on auscultation but evidence of the rate may be detected by examination of the jugular inlet. Periodically, as the atrium contracts during the period that the atrioventricular valves are closed, atrial cannon waves may occur up the jugular vein. There is usually variation in the intensity of the first heart sound due to variation in ventricular filling. Affected animals show extremely poor exercise tolerance and usually have evidence of generalized heart failure. There is frequently a history of syncopal attacks.

The electrocardiogram shows a slow and independent ventricular rate characterized by QRS complexes that are completely dissociated from the faster P waves.

The prognosis in complete heart block is extremely grave unless it is associated with a correctable electrolyte imbalance. The animal should be kept at rest in quiet surroundings while every effort is made to correct the underlying cause. Corticosteroids and dextrose are usually given intravenously in an attempt to reduce the severity of the initiating myocardial lesion. Isoproterenol (isoprenaline) may stimulate higher nodal tissue and may increase the heart rate. Isoproterenol is usually infused intravenously at a concentration of 1 mg/L of infusion fluid and the rate of infusion is adjusted to effect. This is not a practical treatment in most situations. The use of an internal pacemaker has been reported in the horse but would clearly make the animal unsuitable for athletic endeavors.

Atrioventricular block and atrioventricular dissociation may develop during anesthesia and can be associated with arrhythmogenic anesthetic drugs, hypercapnia, hypoxia and electrolyte and acid–base imbalances. In these circumstances, the administration of regular doses of atropine (0.02 mg/kg) may not alleviate the arrhythmia. Dopamine HCl infusions (3–5 µg/kg per min) have been effective.

The Wolff–Parkinson–White syndrome is recorded as a rare observation in cattle.

PREMATURE COMPLEXES
Premature complexes or extrasystoles arise by the discharge of impulses from irritative foci within the myocardium. They are classified according to the site of their origin as atrial, junctional and ventricular premature complexes. It is often not possible to distinguish between these by physical examination, particularly at fast heart rates. However, auscultation of an animal with premature beats usually reveals an occasionally irregular rhythm.

Atrial premature complexes
These arise from the discharge of an ectopic atrial pacemaker outside the sinus node. Atrial premature contractions are
Ventricular premature complexes

Ventricular premature complexes may arise from an irritant process anywhere within the ventricular myocardium. The normal rhythm is interrupted by a beat that occurs earlier than expected but the initial rhythm is established following a compensatory pause. This can be established by tapping through the arrhythmia as described earlier. The heart sounds associated with the premature beat are usually markedly decreased in amplitude while the first sound following the compensatory pause is usually accentuated. Occasionally, ventricular premature complexes may be interpolated in the normal rhythm and not followed by a compensatory pause. If the diastolic filling period preceding the premature beat is short the pulse associated with it will be markedly decreased in amplitude or even absent.

On the electrocardiogram ventricular premature complexes are characterized by bizarre QRS morphology (Figure 8.1). Conduction over nonspecialized pathways results in a complex of greater duration and amplitude to normal and the complex slurs into a T wave that is also of increased duration and magnitude. The vector orientation depends on the site of the ectopic foci initiating the contraction but it is invariably different from that of normal contractions. Electrocardiographic examination allows a differentiation of the site of origin of premature complexes and further subclassification within the categories.

Premature complexes of all site origins are indicative of myocardial disease, the one exception being the occurrence of atrial premature complexes accompanying cases of gastrointestinal disease in cattle. Atrial premature complexes occur commonly in cattle with gastrointestinal disease and their presence should be suspected whenever there is a variation in the intensity of the first heart sound with or without an underlying detectable cardiac irregularity. Atrial premature complexes can progress to atrial fibrillation in these cases where there is excessive vagal tone.

Horses in which premature beats are detected or suspected should be examined after careful exercise, which will usually increase the occurrence and severity of the arrhythmia. Premature beats are most easily detected during the period of slowing of heart rate after exercise.

**REFERENCES**

**ARRHYTHMIAS WITH TACHYCARDIA**

An excitable focus within the myocardium may spontaneously discharge and cause depolarization of the remaining myocardium. If the discharge rate approaches or exceeds that of the sinus node the focus may transiently take over as the pacemaker of the heart.

**PAROXYSMAL TACHYCARDIA**

Paroxysmal tachycardia may arise from an irritant focus within the atria or the ventricles but in large animals ventricular paroxysmal tachycardia is more common. Atrial paroxysmal tachycardia (Figure 8.1) and atrial flutter are rare and are transients leading to atrial fibrillation.

In paroxysmal tachycardia the increase in heart rate is abrupt and the fall to normal is equally sudden. This characteristic usually serves to distinguish this arrhythmia from the transient increases in heart rate that may normally follow such factors as excitement. Also the heart rate is elevated to a rate far in excess of that which would be normally expected from such stimuli.

More commonly the excitable focus discharges repetitively over a long period of time to produce more continual ventricular tachycardia associated with ventricular extrasystoles. Sustained tachycardia is not normal and can lead to myonecrosis; three parturient dairy cows with sustained tachycardia (heart rate > 120 beats/min) had multifocal areas of necrosis throughout the myocardium characterized by myofibrillar lysis and disarray.

**VENTRICULAR TACHYCARDIA**

Ventricular tachycardia may produce either a regular heart rate or an irregular heart rate and rhythm.

When the discharge rate of the irritant focus far exceeds that of the sinoatrial pacemaker, the ectopic focus will take over completely as the pacemaker of the heart and on examination of the cardiovascular system a rapid but regular heart rate and pulse is detected and there is no irregularity of rhythm or of pulse amplitude or intensity of heart sounds. This is known as ventricular tachycardia with atrioventricular dissociation. This abnormality is easily overlooked clinically but
should be suspected in any adult horse or cow where the heart rate exceeds 90 beats/min and is frequently the cause of heart rates in excess of 120 beats/min. Ventricular tachycardia should also be suspected where the heart rate is elevated to a level that is higher than that expected from the animal’s clinical condition.

An electrocardiogram gives the diagnosis based on the occurrence of multiple regular QRS complexes with abnormal amplitude and duration of the QRS and T complexes and the T wave oriented in a direction opposite to the QRS complex (Figure 8.1). P waves may be detected on the electrocardiogram but they have no relationship to the QRS-T complex and are frequently lost within them.

When the discharge rate of the irritant focus within the myocardium is similar to that of the sinoatrial node the ventricular tachycardia can be manifested by a gross irregularity in rhythm. This is a common manifestation in large animals. In this situation many of the discharges which originate in the sinus node are transmitted to the ventricle during a refractory period from a previous ectopic focus, but some reach the ventricle when it is not in a refractory state and are conducted normally. At some periods ventricular complexes may be initiated by the discharges from both sites.

The varying influence of each pacemaker on ventricular contraction produces a marked irregularity in cardiac rhythm and it is frequently not possible to establish clinically a regular pattern to the heart rhythm. Variations between beats in the degree of atrial filling and in the diastolic filling period will result in a marked variation in the intensity of the heart sounds and in the amplitude of the pulse. Frequently at fast heart rates there is a pulse deficit. Cannon atrial waves can be observed in the jugular vein when atrial contraction occurs at the same time as a ventricular extrasystole.

The electrocardiogram shows runs of extrasystoles interspersed with normally conducted complexes and usually the presence of fusion beats.

Ventricular tachycardias are evidence of severe cardiac disease and are usually accompanied by signs of acute heart failure. They may result from primary myocarditis, nutritional cardiomyopathy, or myocardial neoplasia or be secondary to valvular disease and myocardial ischemia. Ventricular arrhythmias are common in certain plant poisonings and other toxicities, and in severe electrolyte and acid-base disturbance, and commonly occur in the final stages of heart failure. If uncorrected, ventricular tachycardia may lead to ventricular fibrillation and death and frequently specific antiarrhythmic therapy is indicated during the period that the prime cause is being corrected.

**Treatment**

**Lidocaine** is the drug of first choice for treating hemodynamically important ventricular arrhythmias in large animals. Lidocaine is an antiarrhythmic agent of class 1b of Vaughan-Williams’s classification, and slows intracardiac conduction by blocking the fast sodium channel while shortening the refractory period of myocardial tissue. Typically, lidocaine is given as an intravenous bolus at 0.5–1.0 mg/kg BW every 5 minutes for a total of four treatments (total dose 2–4 mg/kg BW). Lidocaine has the advantages of widespread availability, low cost and low cardiovascular toxicity, with the major disadvantage being its very short duration of action (half-life is 40 minutes in the horse). The most commonly seen initial sign of lidocaine toxicity is muscle fasciculations, which occur at a serum lidocaine concentration of 1.9–4.5 mg/L. If infusion is continued, sedation and altered visual function are apparent, the latter being manifest as rapid eye blinking, anxiety and attempts to inspect closely located objects. Temporary recumbency, excitement, sweating and convulsions occur with higher doses.

**Quinidine sulfate** is the drug of second choice for use in horses. Quinidine is an antiarrhythmic agent of class 1a of Vaughan-Williams’s classification, and slows intracardiac conduction by blocking the fast sodium channel and prolongs the action potential duration. An initial dose of 20 mg/kg is given orally, followed by a dose of 10 mg/kg given every 8 hours. The drug is not effective until 1–2 hours following administration. Intravenous quinidine gluconate (0.5–2.2 mg/kg BW bolus every 10 minutes to a total of 12 mg/kg BW) may be of greater value in those rare instances when oral quinidine is not indicated. Serum quinidine concentrations of 4 mg/L appear effective in treatment of cattle with ventricular tachycardia but serum concentrations following an oral dose of 20 mg/kg vary widely between cows and slow intravenous infusion is the preferred method of therapy. There is a very narrow therapeutic index in cattle and death can occur in some cows at doses that are therapeutically effective in others. Quinidine treatment in cattle should be approached with caution.

**Phenytoin sodium** is a good alternative to quinidine sulfate, and has been effective in treating ventricular arrhythmias in horses. Phenytoin is an antiarrhythmic agent of class 1b of Vaughan-Williams’s classification (same as lidocaine), and slows intracardiac conduction by blocking the fast sodium channel while shortening the refractory period of myocardial tissue. The recommended dosage protocol for the horse requires an initial oral dose of 20 mg/kg BW every 12 hours for four doses, followed by a maintenance oral dose of 10–15 mg/kg BW every 12 hours, with monitoring of phenytoin plasma concentrations. Plasma concentrations of 5–10 mg/L appear to be effective in treatment of horses with ventricular tachycardia. High plasma phenytoin concentrations are associated with sedation, recumbency and excitement, and the dosage protocol should be altered in horses that appear sedated. The major advantage of phenytoin over lidocaine is its long duration; conversely, its major disadvantage is the initial time required (2–6 h) to exert an antiarrhythmic effect. An intravenous form of phenytoin sodium has been administered to a pony with digitalis-induced ventricular arrhythmias, but the alkaline pH of the infused solution carries a high risk of thrombophlebitis.

**Magnesium sulfate** (0.004 mg/kg BW boluses intravenously at 5-minute intervals to a maximum dose of 0.05 mg/kg BW) has also been successful in treating ventricular arrhythmias either alone or in combination with other antiarrhythmic agents; however, clinical experience with magnesium sulfate administration in horses is minimal.

The severity of ventricular tachycardia is augmented by factors that increase sympathetic tone, and affected animals should be kept in quiet surroundings.

**VENTRICULAR FIBRILLATION**

Ventricular fibrillation is not usually observed clinically. It occurs in the terminal stages of most suddenly fatal diseases, including lightning stroke, plant poisonings such as acute *Phalaris* toxicity, overdose with anesthetics, severe toxemia and in the terminal phases of most acquired cardiac diseases. There is complete absence of the pulse and heart sounds, the blood pressure falls precipitously and the animal rapidly becomes unconscious and dies within a minute or two of onset. Treatment is usually impractical although deaths during anesthesia may be prevented by immediate and aggressive external cardiac massage. Electrical defibrillation is not feasible in large animals due to the bulk of the animal and the current required. Intracardiac injections of epinephrine are often used in acute cardiac arrest but do not correct fibrillation and are of little value.

**ATRIAL FIBRILLATION**

In atrial fibrillation atrial depolarization is characterized by numerous independent fronts of excitation that course continuously and haphazardly through the
atria. There is no synchronous atrial contraction and atrioventricular nodal stimulation occurs in an irregular and random fashion. The effects within the atria cannot be appreciated on auscultation and the clinical detection of this arrhythmia occurs through its effects on ventricular function. The random stimulation of the ventricles produces a heart rate and pulse that is irregularly irregular. It is not possible to establish any basic rhythm by tapping out this arrhythmia and the rate varies from period to period.

Because there is no atrial contraction, filling of the ventricles is entirely passive and very much dependent on diastolic filling time. Some contractions occur very quickly following the preceding contraction with little time for diastolic filling and this produces a marked variation in the intensity of the heart sounds and in the amplitude of the pulse. At fast heart rates there will be a pulse deficit. There is no fourth heart sound (S4) or atrial wave at the jugular inlet because there is no coordinated atrial contraction, but the third heart sound is usually grossly accentuated. The degree of cardiac insufficiency that results from this arrhythmia varies and depends upon the general rate at which the ventricles beat at rest. This is determined primarily by vagal activity.

On the electrocardiogram there are no P waves discernible but the baseline shows multiple waveforms (f waves) that occur with a frequency of between 300 and 600 beats/min (Figure 8.1). QRS–T complexes are normal in configuration but there is wide variation and no pattern in the Q–Q intervals. Atrial fibrillation is one of the more common arrhythmias in large animal species.

Atrial fibrillation in the horse
Horses with atrial fibrillation fall into two categories. In one category, sometimes called "benign fibrillators," there is no evidence of underlying heart disease whereas in the other, there is.

Benign fibrillation
In cases that are benign fibrillators the vagal tone may be high and conduction through the atrioventricular node is suppressed to result in heart rates in the region of approximately 26–48 beats/min. At this rate there is no cardiac insufficiency at rest and hemodynamic parameters are normal." At this rate the horse can elevate its heart rate with exercise to allow moderate performance, although it will never perform satisfactorily as a racehorse. This is the most common manifestation in this species and it is typified by a gross irregularity in rate, rhythm and intensity of the heart sounds and by the occurrence, at rest, of occasional periods lasting for 3–6 seconds where there is no ventricular activity. At very slow rates periodic syncope may occur.

The benign form of atrial fibrillation occurs not infrequently in draft horses and is also seen in racehorses. A survey of 106 cases of atrial fibrillation in horses found the disease most commonly in Standardbreds and Thoroughbreds under 7 years of age, with a high proportion under 4 years of age, which may have been a reflection of the admissions to the clinic rather than real age incidence. Exercise intolerance was the most common clinical history. All horses had an irregular heart rate and rhythm and the pulse and intensity of the heart sounds were variable. A separate study of 67 horses showed a significantly higher prevalence in Standardbreds and Thoroughbreds than other breeds of horse and a significant difference in the mean age at diagnosis between Standardbreds (4 years) and Thoroughbreds (9 years).

Racehorses commonly have a history of normality at rest but poor exercise tolerance following a race in which the horse ran well for the first 200–300 m but subsequently faded badly and finished a long way behind the field. Paroxysmal atrial fibrillation has also been observed in the horse under these circumstances. Horses with paroxysmal atrial fibrillation show atrial fibrillation when examined immediately following the race, but convert to normal sinus rhythm shortly after and have normal cardiovascular function if the examination as to cause of poor racing performance is delayed. A large scale study of 39 302 racehorses undergoing 404 090 race starts estimated a minimum prevalence of atrial fibrillation of 0.29%. The estimated prevalence was higher (1.39%) in horses that finished slowly or did not finish, and the prevalence increased markedly with age. Atrial fibrillation was paroxysmal in most horses, with 93% of horses with atrial fibrillation spontaneously converting to sinus rhythm within 24 hours of the race. Attempted conversion of horses with atrial fibrillation should therefore be delayed for at least a couple of days following a race, because most will convert spontaneously without treatment.

There is debate as to the cause of the benign form of atrial fibrillation and whether myocardial and vascular lesions are present in the atria of a significant proportion of animals with this arrhythmia. However, the high rate at which atrial fibrillation converts spontaneously or by treatment to be followed by successful racing performance suggests that this arrhythmia frequently occurs in young horses in the absence of significant atrial pathology. Benign atrial fibrillation in young racing horses therefore has many similarities to atrial fibrillation in lactating dairy cattle with abdominal disease, in that it is likely that most cases do not have underlying heart disease. The increased prevalence of atrial fibrillation in race horses with age suggests, however, that underlying heart disease does predispose to developing atrial fibrillation during a race.

Underlying disease
Horses may develop atrial fibrillation at fast heart rates in response to underlying cardiovascular disease. Commonly this is mitral valve insufficiency, tricuspid valve insufficiency or a combination of both but any acquired or congenital lesion that results in atrial hypertrophy has this risk.

Where there is underlying heart disease the ventricular rate at rest is much higher and the arrhythmia presents as a tachycardia. It has been suggested that a heart rate greater than 60 beats/min is indicative of underlying cardiac disease in cases of atrial fibrillation. In horses with atrial fibrillation ventricular filling is impaired at heart rates above 70 beats/min and at resting heart rates above 80–100 beats/min there is severe cardiac inefficiency and the animal rapidly develops signs of cardiac failure.

Primary pulmonary hypertension as a cause of atrial fibrillation is also recorded in horses, the increased resistance to right ventricular outflow leading to ventricular hypertrophy and dilatation, stretching of the right atrioventricular annulus, atrial dilatation and subsequent atrial fibrillation.

Paroxysmal atrial fibrillation has been observed in newborn foals showing signs of respiratory distress and with birth anoxia.

Atrial fibrillation in the cow
Atrial fibrillation in the cow may occur secondary to myocardial disease or endocarditis resulting in atrial enlargement, but more commonly is functional in occurrence and traditionally has not been associated with clinically detectable cardiac lesions. However, a recent histopathological study in nine Holstein-Friesian cows with atrial fibrillation and 12 healthy controls in sinus rhythm indicated that multifocal or large areas of myocardial fibrosis were present more frequently and with greater severity in cattle with atrial fibrillation than healthy controls. Interestingly, the atrial lesions
were largely confined to the dorsal regions of the cranial lateral and medial regions of the right atrium. Organic heart disease therefore appears to predispose cattle to the development of atrial fibrillation, and an atrial fibrillation prevalence of 2.5% was recorded in apparently healthy lactating dairy cows over a 18 month period. In large cross sectional study, atrial fibrillation was not observed during a 3-5 minute ECG recording in 952 of dairy cattle aged 1 or more years.

In sick cattle, atrial fibrillation most commonly occurs in association with gastrointestinal disease, abnormalities causing abdominal pain and metabolic disease. Abnormalities as diverse as acute enteritis, left displacement of the abomasum and torsion of the uterus may be accompanied by this arrhythmia. Heightened excitation of the atria, in association with electrolyte and acid-base disturbances or due to change in vagal tone, has been postulated as a cause, and atrial premature complexes are also seen in the same types of clinical case. (Figure 8.1) The administration of neostigmine to cattle with gastrointestinal disease may precipitate the occurrence of atrial fibrillation. The arrhythmia usually converts spontaneously to sinus rhythm with correction of the abdominal disorder.

Atrial fibrillation in the sheep and goat
This may occur as a result of incompetence of the tricuspid or mitral valves, the presence of myocarditis or, in goats, as a sequel to interstitial pneumonia along with cor pulmonale. The presenting signs are those of respiratory distress and heart failure. Ascites is prominent and there is marked jugular distension with an irregular jugular pulse.

Treatment of atrial fibrillation
Ruminants
Ruminants with atrial fibrillation are not in general treated with specific antiarrhythmic drugs as the heart will usually revert to sinus rhythm following the correction of the underlying abdominal disorder and sufficient time (at least 1 week after return to normal physical health). However, the intravenous administration of quinidine (49 mg of quinidine sulfate/kg BW, at 0.20 (mg/kg)/min) was successful in converting seven of nine cows to normal sinus rhythm at a mean plasma quinidine concentration of 3.6 µg/mL. Oral quinidine administration is not effective in ruminants because of the poor oral bioavailability. Side effects of intravenous quinidine administration in cattle include depression, ataxia, blepharospasm, diarrhea and increased frequency of defecation. Response to treatment in sheep and goats is poor, although one ram was successfully converted to normal sinus rhythm using electrical cardioversion using 360 J and paddles placed over the right heart base (behind the triceps muscles) and the left cardiac apex close to the sternum.

Horses
Horses with atrial fibrillation at high heart rates are generally not treated successfully as serious cardiac pathology is usually present. Digoxin and quinidine sulfate are used. The decision to treat a horse with atrial fibrillation at low heart rates depends upon the requirement for the horse to perform work, because horses with this arrhythmia can be retired and will live for several years. They may be used successfully as brood mares.

Horses with benign atrial fibrillation can be converted to normal sinus rhythm with subsequent return to successful racing or other performance. Oral quinidine sulfate is usually used. Quinidine is an antiarrhythmic agent of class 1a of Vaughan-Williams’s classification, slows intracardiac conduction by blocking the fast sodium channel and prolongs the action potential duration. Several dose regimens have been used, but the administration of an oral dose of 22 mg/kg every 2 hours until conversion is achieved or toxicity is manifest has proved effective. In the majority of cases, conversion will occur before the total dose exceeds 40 g. Toxicity is likely when the total dose exceeds 60 g and the decision to continue with therapy once this dose has been reached should be considered carefully. The plasma quinidine concentration required for cardioversion ranges from 2–4 µg/mL and toxicosis has been reported at 5 µg/mL.

Toxicity is not uncommon with quinidine therapy and separate studies report 48% and 28% of horses with some form of adverse reaction. Depression, ataxia, anorexia, urticaria, congestion of the mucous membranes, colic and death are recorded. Prolongation of the QRS interval to 25% greater than pre-treatment values has been considered a monitor for cardiovascular toxicity. The toxic effects of quinidine may be corrected by intravenous administration of sodium bicarbonate in an attempt to increase the percentage of quinidine bound to protein. Such treatment runs the risk of inducing hypokalemia, which may exacerbate quinidine toxicity. Some prefer to digitalize the horse intravenously prior to medication with quinidine in an attempt to reduce tachyarrhythmias at the point of conversion and those associated with quinidine toxicity. Nephrotoxicity with uraemia and diarrhea can occur at lower doses. Nephrotoxicity is transient and repairs rapidly following withdrawal of the drug but the serum urea nitrogen concentration and urine should be monitored during therapy in addition to cardiovascular function.

There is a much greater success rate with conversion in young horses and when it is attempted shortly following the onset of the arrhythmia. If the arrhythmia has been present for more than 4 months, successful conversion is much less common, and side effects with therapy are more common. Following cardioversion the horse should be rested for 3 months. In some horses the conditions recur after a period of racing and repeated conversions with quinidine are possible. Conversion by intravenous quinidine gluconate is reported in the horse using an initial dose of 1.0–15 mg/kg, given over a period of 1 minute and repeated every 5–10 minutes until sinus rhythm is restored or the QRS interval increases 25% over baseline, ventricular rate exceeds 90 beats/min, signs of toxicity occur or a total dose of 11 mg/kg has been administered. Conversion by quinidine and atrial pacing is also recorded in the horse.

Oral and intravenous flecainide has been used with mixed success to convert horses in atrial fibrillation. Flecainide is an antiarrhythmic agent of class 1c of Vaughan-Williams’s classification, slows intracardiac conduction by blocking the fast sodium channel and shortens the refractory period of the Purkinje fibers. Intravenous administration of flecainide acetate (1–2 mg/kg BW) infused at 0.2 (mg/kg BW)/min was effective in converting experimentally-induced atrial fibrillation in six horses and naturally occurring atrial fibrillation in two horses. The plasma flecainide concentration at the time of conversion was 1.3 mg/L. Oral administration of flecainide acetate (4–6 mg/kg BW) also produced plasma flecainide concentrations that approximated 1.3 mg/L for a number of hours. However, in a subsequent study in 10 horses with naturally occurring atrial fibrillation, intravenous flecainide failed to convert nine horses with long-standing atrial fibrillation to sinus rhythm, but did convert one horse who had been in atrial fibrillation for 12 days. Oral administration of quinidine sulfate subsequently converted eight of the nine horses to normal sinus rhythm. Two horses administered flecainide developed potentially dangerous ventricular arrhythmias during treatment.

One horse was converted from atrial fibrillation using rectilinear biphasic electrical cardioversion, which was safer
than conventional monophasic electrical cardioversion. General anesthesia is induced using agents that produce minimal cardiovascular depression (such as intravenous induction with guaifenesin, diazepam and ketamine and maintenance with sevoflurane). The front legs of the horse were extended and cardioversion-deblirrillation pads were placed over both sides of the shaved thorax, directly over the atria, the position of which had been determined ultrasonographically. The horse converted to normal sinus rhythm after delivering 200 J in conjunction with a small amount of intravenous quinidine. Three horses were converted from atrial fibrillation using transvenous electrical cardioversion via placement of a custom-length 6.5 French bipolar catheter using ultrasonographic guidance. Catheter placement was manipulated so that one electrode was in the pulmonary artery and the other electrode in the vicinity of the right atrium. Cardioversion was accomplished at 125–300 J using a biphasic truncated exponential shock delivered to be not coincident with the T wave. Concurrent use of antiarrhythmic medications was not required. The use of electrical cardioversion should be considered in cases of atrial fibrillation refractory to oral or intravenous quinidine administration.

REVIEW LITERATURE

Diseases of the heart

MYOCARDIAL DISEASE AND CARDIOMYOPATHY

Etiology
Certain bacterial, viral, parasitic infections, some nutritional deficiencies and toxic agents

Epidemiology
Specific to causative agent

Clinical findings
Reduction of cardiac reserve and decreased exercise tolerance, cardiac arrhythmias, congestive heart failure or acute heart failure

Clinical pathology
Electrocardiography, echocardiography and serum cardiac troponin I concentrations. Other examinations directed at determining the specific cause

Necropsy findings
Myocarditis, myocardial degeneration

Treatment
For cardiac insufficiency. Specific therapy, if available, for specific cause

ETIOLOGY
A number of diseases are accompanied by inflammation, necrosis or degeneration of the myocardium. These include several bacterial, viral or parasitic infections and some nutritional deficiencies and toxicities. In most cases, the involvement of the myocardium is only part of the total spectrum of these diseases, although the cardiac manifestations may be clinically pre-eminent. The term cardiomyopathy is generally restricted to those diseases where myocardial damage is the prime manifestation. Causes of myocardial dysfunction include the following.

Bacterial myocarditis
- Following bacteremia, as in strangles or from navel-ill
- Tuberculosis – especially horses
- Tick pyemia in lambs
- Clostridium chauvoei
- Histophilus somni
- Extension from pericarditis, epicarditis or endocarditis

Viral myocarditis
- Foot-and-mouth disease – especially young animals
- African horse sickness
- Equine viral arteritis
- Equine infectious anemia
- Equine herpesvirus-1 in fetus
- Swine vesicular disease
- Parvovirus in piglets
- Encephalomyocarditis virus infection in pigs
- PRRS virus in piglets
- Bluetooge in sheep

Parasitic myocarditis
This is primarily associated with Strongylus spp. (migrating larvae) cysticercosis, Sarcozystis spp. and Neospora caninum (in the neonatal calf). In a postmortem study of over 2000 equine hearts, 15% showed myocardial fibrosis in association with occlusive angiopathic change. No age association was found, but recent infarcts were more common in yearlings. It was postulated that these lesions result from thromboemboli from verminous plaques in the proximal thoracic aorta.

Nutritional deficiency
- Vitamin E/Selenium deficiency in all large animal species
- Some forms of chronic copper deficiency in cattle (falling disease) – experimental copper deficiency in swine
- Iron deficiency in piglets and veal calves
- Copper/cobalt deficiency in lambs

Toxicity
- Inorganic poisons – selenium, arsenic, mercury, phosphorus, thallium
- Gossypol from cotton seed cake
- The mycotoxin fumonisin when ingested by pigs and horses
- Fluoroacetate (1080) and poisoning by Acacia georgiana, Castorobium and Oxytobium spp., Dichapetalum cyclosium
- Plants and weeds, including members of Ixiloena, Pachystigma, Fracture, Asclepias, Gericarpa, Cryptostegia, Albizia, Cassia, Digitalis, Urechites, Pimelea, Astragalus, Fadogia, Cicuta, Colchicum, Karwinskia, Vicia, Cicuta, Trigonella, Bryophyllum, Pulicaria, Lupinus, Lantana, Kalanchoe, Homeria, Hymenoxys, Eupatorium spp.
Venoms
- Rattlesnake (*Crotalus* spp.) venom in horses
- *Vipera palaestinae.*

Embolic infarction
- Emboli from vegetative endocarditis or other embolic disease such as bracken fern poisoning in cattle.

Tumor or infiltration
- Viral leukemia of cattle
- Other cardiac neoplasia
- Cardiomyopathy in horses due to amyloid infiltration of the myocardium.¹

Inherited
- Malignant hyperthermia of swine
- Hypertrophic cardiomyopathy in swine
- Congenital cardiomyopathy of Polled Hereford and Horned Hereford calves with dense curly coats, and Japanese Black calves
- Inherited cardiomyopathy in adult cattle occurring in Red Holstein–Simmental crossbred cattle in Switzerland and Austria, Red Danish dairy cattle in Denmark, Holstein–Friesian cattle in the UK, Austria, Denmark, Sweden, Japan, Canada and Australia (see cardiomyopathy – inherited as an autosomal recessive gene)
- Glycogen storage disease – α-1,4-glucosidase deficiency in Shorthorn and Brahman cattle and Corriedale sheep.

Unknown or uncertain etiology
- Myocardial necrosis and hemorrhage secondary to acute lesions in the central nervous system³
- Exertional rhabdomyolysis of horses, capture myopathy of wild ruminants, restraint stress in swine
- Sudden death in young calves associated with acute heart failure and myocardial necrosis and precipitated by periods of intense excitement such as that experienced at feeding time⁴,⁵
- Myocardial lipofuscinosis (brown atrophy) in aged or cachetic cattle, especially Ayshires, but often found in healthy animals at slaughter⁶
- Myocardial disease following mild upper respiratory disease in horses, especially when training or exercise is continued through the respiratory disease episode.

**PATHOGENESIS**
The primary effect of any myocardial lesion is to reduce cardiac reserve and limit compensation in circulatory emergencies. Minor lesions may only reduce performance efficiency while more severe lesions may produce greater clinical effect.

Most commonly, myocardial disease results in arrhythmias and conduction disturbances from primary involvement of the conduction system or establishment of excitatory foci within the myocardium. While the animal is at rest there may be minimal evidence of cardiac disease but catastrophic disturbances in cardiac conduction may occur under the adrenergic influences of exercise or excitement. The effects of pharmacological cardiotonic agents in poisonous plants are frequently also initially manifest when the animals are moved or otherwise excited.

Endogenous or synthetic catecholamines, in their own right, can produce multifocal myocardial necrosis, especially in the left ventricle.⁷ Sympathetic overactivity and local catecholamine release in the myocardium has been postulated as the cause of myocardial disease accompanying acute brain lesions in domestic animals and myocardial disease associated with some forms of stress and overexertion.⁸,⁹

Myocardial disease may also result in congestive heart failure through its primary effect on the myocardium and the function of the heart as a pump.

**CLINICAL FINDINGS**
In early cases, or cases with mild or moderate myocardial damage, a decreased exercise tolerance is the usual initial presenting sign. This is usually accompanied by an increase in heart rate and heart size, although the latter may only be detectable by echocardiography.

There may be clinically recognizable arrhythmia, particularly tachyarrhythmias associated with multiple ventricular ectopic foci. The characteristics of the

**Clinical Pathology**
Electrocardiography and echocardiography are used in special examination. Hematological examination, blood culture and serology may be of value in determining the cause of myocardial disease and a full biochemical profile is advisable to determine if multisystemic problems are present. Myocardial infarction and necrosis may be associated with the release of cell enzymes into the bloodstream during the acute phase and the determination of the serum activities of lactate dehydrogenase, creatine kinase and aspartate aminotransaminase are of value.⁹,¹⁰

The cardiospecific isoenzyme troponin I provides the most sensitive and specific indication of cardiac necrosis (see chronic heart failure section) whereas the predictive value of serum creatinine kinase and lactate dehydrogenase activities is much lower.¹¹,¹² Toxicological examination and tests for nutritional trace element deficiencies may be indicated.

**NECROPSY FINDINGS**
Bacterial infections may cause discrete abscesses or areas of inflammation in the myocardium but viral infections and degeneration due to nutritional deficiencies and poisonings usually produce a visible pallor of the muscle, which may be uniform or present as streaks between apparently normal bundles of muscle. In acute cases, there may be petechial or linear hemorrhages in the myocardium. Calcification may occur in areas of myocardial damage and with enzootic calcinosis and vitamin D toxicity. The nature and distribution of myocardial damage within the heart can vary according to the inciting agent and this can be an aid to diagnosis. The degenerated muscle may also be present in only the inner layers of the wall, leaving the external layers with a normal appearance.
In coronary thrombosis infarction of a large area of the wall may have occurred but this is not visible unless the animal survives for at least 24 hours afterwards. Careful examination of the coronary arteries is usually necessary to detect the causative embolus. In horses infarction occurs most commonly in the right atrium. The terminal stage of myocardial degeneration or myocarditis is often fibrous tissue replacement of the damaged tissue. The heart is flabby and thin-walled and shows patches of shrunken, tough fibrous tissue. Rupture of the atrial walls may result, with sudden death occurring as a result of the pressure of blood in the pericardial sac. The lesions of lymphomatosis are characteristic of this disease: large, uneven masses of pale, firm, undifferentiated tissue with the consistency of lymphoid tissue. Focal myocardial fibrosis, possibly resulting from microembolism from strongyle-induced endarteritis, is common in healthy horses but has also been ascribed as the predisposing factor to conduction disturbances such as atrial fibrillation and heart block.13

DISEASES OF THE HEART 423

RUPTURE OF THE HEART AND ACUTE CARDIOVASCULAR ACCIDENTS

Rupture of the heart occurs rarely in animals. It is recorded in cattie where a foreign body penetrating from the reticulum perforates the ventricular wall, and in the left atrium of horses as a consequence of chronic fibrotic myocarditis.1 Rupture of the base of the aorta is not uncommon in horses and has the same effect as cardiac rupture. The pericardial sac immediately fills with blood and the animal dies of acute heart failure due to pericardial tamponade. A similar cardiac tamponade occurs when reticular foreign bodies lacerate a coronary artery or when foals suffer severe laceration of the epicardium during a difficult parturition.

RUPTURE OF THE AORTA

When the aorta ruptures it may do so through its wall just above the aortic valves. The wall may have been weakened previously by verminous arteritis associated with migrating strongyles in horses or onchocerciasis in cattle or by the development of medionecrosis. Another form of rupture occurs through the aortic ring. Death occurs very suddenly; all cases reported by one author affected stallions and coincided with the time of breeding. Cardiac tamponade may occur but the common finding is a dissecting aneurysm into the ventricular myocardium.

Rupture of the aortic arch and the pulmonary artery near the ligamentum arteriosum occurs occasionally in horses. The resultant fistula between the aorta and the pulmonary artery produces a sudden onset of cardiac failure and respiratory distress. Affected horses usually die shortly after the onset of clinical signs but can survive up to 8 days. The rupture is predisposed by abnormalities in the vasa vasorum of the vessels and may have a familial occurrence.2

Aortocardiac fistulas originating at the right aortic sinus are recorded in a series of older horses with sudden onset acute distress and exercise intolerance.3 Five of the seven horses had a characteristic continuous murmur that was loudest at the right fourth intercostal space. Fistulas extended into the right ventricle or atrium in six horses and the left ventricle in one. Five had dissecting tracts in the septal myocardium. Rupture of the aorta is the usual cause of death in calves with Marfan's syndrome. Some have dissecting aneurysms of the aorta and pulmonary artery. Calves with Marfan's syndrome are affected from birth. They have a loud systolic murmur over the base of the heart on the left side in association with enlargement of the aortic root. There are other phenotypic abnormalities, including long thin limbs, joint and tendon laxity, and ocular abnormalities including dorsal displacement of the lens and lens opacity. The nature of the inheritance in cattle is uncertain.5

Craniomesenteric artery aneurysms have been reported in cattle less than 4 years of age secondary to inherited defects in the wall of the celiac and cranial mesenteric arteries. An autosomal dominant mode of inheritance was suspected.5 An aneurysm of the cranial mesenteric artery was diagnosed in a cow with severe abdominal pain and the presence of a large pulsatile mass at the root of the mesentery.6

RUPTURE OF HEART VALVES

Sudden death, or sudden onset of acute heart failure can also result from rupture of components of the heart valves. Rupture of the chordae tendineae of the mitral valve occurs in horses both without apparent predisposing lesions and as a sequel to endocarditis and occurs in adult horses as well as foals.2,7 It is manifested by sudden onset of acute heart failure in horses apparently previously healthy or, when a complication of a pre-existing endocarditis, as a sudden onset complication of the disease or a cause of death. The rupture may involve the chordae of any of the cusps of the valve.2 Rupture of the pulmonary valve producing right heart failure can also occur.10

REFERENCES

COR PULMONALE

Cor pulmonale is the syndrome of right-sided heart failure resulting from an increase in right heart workload secondary to increased pulmonary vascular resistance.
and pulmonary hypertension. The most documented cause of pulmonary hypertension in livestock is **alveolar hypoxia**. Acute alveolar hypoxia (lowered alveolar PO\textsubscript{2}) is a potent cause of pulmonary hypertension in several species, but cattle are especially reactive and this is the cause of the syndrome of cor pulmonale in cattle at high altitudes, **bovine brisket disease**, which is described in more detail elsewhere in this text.

An outbreak of cor pulmonale with pulmonary vascular lesions similar to those seen with high mountain disease but occurring in calves not at altitude is recorded; it was postulated but not proved to be the result of the ingestion of feed contaminated with the pyrrolizidine alkaloid monocrotaline.\(^1\)

Pulmonary hypertension can also result from partial destruction of the **pulmonary vascular bed** and a reduction in its total cross-sectional area. Pulmonary thromboembolic disease can produce right heart failure by this mechanism. Chronic interstitial pneumonia and emphysema may also induce cor pulmonale by the same mechanism.\(^2\)

**Chronic obstructive pneumonia**, where there is airway constriction and accumulation of fluid in distal airways, may induce pulmonary hypertension by a combination of chronic hypoxia and reduction of the pulmonary vascular bed.\(^3\) Mean pulmonary artery pressures in calves with respiratory disease was 42 mmHg, compared to 22 mmHg in healthy age-matched calves. Although pulmonary hypertension and right heart hypertrophy may occur in livestock with primary pulmonary hypertension, and chronic cardiac insufficiency is usually minor, and right heart failure rare. Nevertheless it can occur and is a cause of congestive heart failure in cattle.\(^4,5\)

In goats, cor pulmonale, with right ventricular and right atrial hypertrophy secondary to interstitial pneumonia, may lead to **atrial fibrillation**,\(^6\) and cor pulmonale leading to atrial fibrillation has also been recorded in horses.\(^7\)

In highly conditioned feedlot cattle, increased intra-abdominal pressure resulting from excessive abdominal fat, fore-stomach engorgement and recumbency can lead to pulmonary hypoventilation, with decreased alveolar PO\textsubscript{2} and subsequent right heart failure, a syndrome analogous to the Pickwickian syndrome in humans.\(^8\)

Chronic severe elevations in pulmonary venous pressure can lead to constriction and hypertrophy of the vascular smooth muscle of precapillary vessels with resultant pulmonary hypertension. An elevated left ventricular filling pressure is perhaps the more common cause and can set the stage for right heart failure in the left heart failure situations. The toxic principle in poisoning by *Pimelea* spp. appears to act in part by constricting the pulmonary venules producing pulmonary hypertension, which contributes to the clinical syndrome.

**Persistent pulmonary hypertension of the neonate** (PPHN) is a common problem in neonatal foals and calves, particularly in calves derived from somatic cell clonal technology. Persistent pulmonary hypertension is characterized by persistent postnatal hypoxemia secondary to failure to adapt to extrauterine life. An imbalance between endogenous vasoconstrictors and vasodilators is believed to play a major role in the development and maintenance of PPHN. An increase in plasma concentration of endothelin-1 (a potent vasoconstrictor) has been observed in neonatal calves with PPHN, and the source of endothelin-1 is thought to be the placenta.\(^9\) Many cloned calves have abnormal placentation, characterized by a reduction in the number of established cotyledons that are enlarged and edematous. Treatment is symptomatic, focusing on intranasal oxygen administration and maintaining the calf in sternal recumbency.

**REFERENCES**

**VALVULAR DISEASE AND MURMURS**

**Etiology**

Valvular disease is acquired or congenital. Endocarditis is the commonest cause. Some murmurs are functional and not indicative of disease

**Epidemiology**

Functional murmurs are common in the horse and vary with breed and training. Little information is available on the epidemiology of acquired valvular disease.

**Clinical findings**

*Murmur* defined by location, timing, character, intensity and radiation. Possibly precordial thrill, cardiac insufficiency and, in severe cases, congestive heart failure

**Clinical pathology**

Blood culture, echocardiography

**ETIOLOGY**

Acquired

- Endocarditis. Most common cause – see following section
- Endocardiosis. Common only in pigs
- Rupture of the chordae tendineae, either spontaneous or secondary to endocarditis\(^1\)
- Laceration, detachment of aortic valve leaflets, either spontaneous or secondary to endocarditis
- Dilatation of the right atrioventricular valve annulus, such as occurs in brisket disease and secondary to some myocardial disease; may result in functional insufficiency of the valves.

**Congenital**

- Pulmonic valve stenosis
- Fenestration of the aortic and pulmonic valves in horses. The cause of the lesions is unknown, although their presence in very young animals, including newborn foals, suggests that some may be congenital defects. The importance of these lesions as causes of valvular insufficiency is doubtful, although they may cause valvular murmurs if they are present close to the attachments of the cusps.
- Blood cysts are common on the atrioventricular valves of cattle. They are lined with endothelium, can occur congenitally\(^2\) and their incidence and size may increase with age.\(^3\) They have no clinical significance. Serious cysts occur occasionally on the mitral valve of cattle.

**EPIDEMIOLOGY**

There is limited information on the epidemiology and the age-specific incidence of valvular disease or murmurs in large animals, although slaughter surveys show a high prevalence of endocardial lesions. Studies at clinical centers indicate that valvular disease is often under-diagnosed in both cattle and horses and that its presence may not be detected in more than 50% of cases.\(^4-6\)

**Horses**

Auscultatory surveys show a high prevalence of murmurs with breed and horse-use differences. Functional (physiological) murmurs are particularly common in trained, fit racehorses. In a survey of 545 clinically normal horses in England, murmurs were heard in 68%, with a higher prevalence in flat racing and National Hunt horses than in competition and pleasure horses.\(^7\) Murmurs with the characteristics of functional ejection murmurs were detected on auscultation over the left hemithorax in approximately 50% of horses and the right side in 8%. Murmurs with the characteristics of early diastolic functional
murmurs were detected on the left side in 15% and on the right side in 13%. Murmurs with the characteristics of regurgitation at the mitral, tricuspid and aortic valves were detected in 3.5, 9.2 and 2.2% of horses respectively.

An extensive abattoir survey\(^*\) suggests that valvular lesions may be more common in the horse than is clinically appreciated. Approximately 25% of horses had lesions, the majority being nodular or distorting lesions on the valves or chordae tendineae of the left side and, in a significant proportion, murmurs were detected prior to slaughter. Chronic trauma of the valve leaflets was considered an important initiating factor.

**Cattle**
A slaughter survey in cattle has reported endocarditis in 5.2 hearts per 10,000 animals.\(^4\)

**Pigs**
In a slaughter survey of pathology in the heart of pigs mitral valve endocardiosis was observed in 63% of pigs and tricuspid endocardiosis in 18% of pigs.\(^9\) The prevalence and severity increases with age. These lesions can be associated with prolapse of the mitral valve and jet impact lesions. They have little significance in growing pigs but the significance of endocardiosis to clinical cardiac disease in older sows needs examination.

Bacterial endocarditis in slaughter pigs has been recorded with a prevalence of 3.1 per 10,000 animals.\(^10\)

**PATHOGENESIS**
The important clinical indications of valvular disease are audible murmurs and palpable precordial thrills. Murmurs may occur at any phase of the cardiac cycle and are caused by the vibrations of turbulent flow of blood transmitted to the surface of the chest. Vibrations of strong intensity may also result in palpable vibrations at the surface of the chest.

**Generation of murmurs**
Blood flow is normally laminar and without turbulence. Turbulence in flow may be produced by a sudden change in the diameter of the vessel through which the blood is flowing. Its occurrence is directly related to the velocity of flow and inversely related to blood viscosity.

Valve lesions
With murmurs associated with valvular lesions the valve lesion produces a sufficient change in stream bed diameter to result in turbulent flow. The turbulence may occur when the valves do not close properly (regurgitation or insufficiency) and blood is forced through atrioventricular orifices during ventricular systole, or through semilunar orifices during ventricular diastole. Turbulence may also occur when the valves do not open completely (stenosis) and blood is forced through a stenotic semilunar orifice during ventricular systole or enters the ventricle through a narrow atrioventricular orifice during ventricular diastole.

The severity of the turbulence and hence the murmur can be increased with higher flow velocities such as occurs with exercise and by factors that decrease blood viscosity such as anemia or hypoproteinemia.

Acquired valvular disease usually results in insufficiency of the affected valve and less commonly both insufficiency and stenosis. Congenital lesions more commonly result in stenosis of the valve.

Murmurs without valvular disease
A change in vessel diameter such as occurs with dilatation of the aorta or pulmonary artery can produce turbulence and a murmur. A reduction in blood viscosity contributes to the frequency of murmurs occurring in anemic and hypoproteinemic states and hemic murmurs are common in anemic cattle, particularly over the pulmonic valve.

**Functional murmurs**
Turbulent flow may occur in the absence of a change in stream bed diameter if a certain critical velocity of flow is exceeded. This is believed to be the cause of functional or ejection murmurs that occur commonly in horses and lactating dairy cows during the rapid ejection phase even at rest and especially following exercise.

**Effects of valvular disease**
Stenosis of the outflow valves results in an increased pressure load on the heart and compensatory hypertrophy (concentric hypertrophy). Insufficiency of the semilunar valves or of the aortic or pulmonic valve produces a volume load on the heart and is followed by compensatory dilatation and hypertrophy (eccentric hypertrophy). If the valves on the left side of the heart are affected, especially the aortic valve, the changes in ejection of the blood from the ventricle produce changes in the character of the peripheral pulse. Involvement of the tricuspid valve will produce changes in the jugular pulse.

Cardiac reserve
The presence of valvular lesions and murmurs may mean little except that some degree of cardiac reserve is lost. This may be small in degree, and moderate stenosis or incompetence can be compensated and supported for long periods. The importance of valvular lesions that do not result in cardiac insufficiency rests in their possible contribution to disease in other organs by the liberation of emboli, and the necessity for close examination of the heart when they are present.

The purpose for which the animal is maintained also has some bearing on the significance of a murmur. Valvular lesions are of much greater importance in racing animals than in those kept for breeding purposes. The challenge to the clinician is to determine the significance of a murmur to the health and performance of the horse and to the safety of the rider.

**CLINICAL FINDINGS**
Only the clinical findings referable to valvular disease are discussed here. The clinical findings in chronic (congestive) heart failure, which may coexist, are discussed elsewhere.

**Technique of examination**
Auscultation is the fundamental basis of examination and a knowledge of the optimum areas of auscultation and the significance of the murmurs encountered are essential. When a murmur is detected it should be categorized according to its timing and duration, intensity, location, and character. There is room for improvement in the correct identification of heart murmurs, and specialist clinicians can more accurately identify the likely site of heart murmurs than other clinicians.\(^11\)

**Timing**
Timing allows a subdivision into systolic, diastolic and continuous murmurs and immediately shortens the list of possible defects present. There is little problem in differentiating systolic from diastolic murmurs at slow heart rates because of the temporal difference between the length of the systolic and diastolic period. However, where there is a murmur present at fast heart rates this distinction is less obvious and it is possible to misclassify the period of the cycle in which the murmur is occurring.

- Murmurs should be timed with reference to the arterial pulse, which occurs in early to mid-systole if a proximal artery is examined
- A convenient artery is on the posteriomedial aspect of the carpus and radius in cattle and horses
- A less satisfactory alternative is timing with the occurrence of the apex beat
- Timing by relation to the heart sounds is unreliable as these are frequently altered in character and at fast heart rates a diastolic murmur may be mistaken for a systolic one
- Systolic murmurs are associated with stenosis of the outflow valves or insufficiency of the atrioventricular valves
- Diastolic murmurs are associated with insufficiency of the outflow
A continuous murmur or one that occurs during both systole and diastole may be associated with both stenosis and insufficiency of the same valve or with multiple valvular lesions but more commonly results from the turbulent flow of blood from a high-pressure to a low-pressure system with no intervening valve, such as occurs with a patent ductus arteriosus.

Duration
Duration during systole or diastole is determined by a careful examination of the murmur with relationship to the period between the heart sounds. Systolic murmurs are further classified as early, late, holo- or pansystolic according to their occurrence and duration in the period between the first and the second heart sounds and diastolic murmurs as early (occurring between S2 and S3), holo-diastolic or presystolic (occurring between the atrial fourth heart sound and S1). Pansystolic and pansystolic murmurs, occurring throughout the systole or diastole, have greater significance than murmurs that occur, for example, only in early systole and early diastole.

Intensity
Intensity or loudness of a murmur provides a guide to its significance. A system of grading the intensity of murmurs that has been found to be of clinical value is as follows:

- Grade I. The faintest audible murmur. Generally only detected after careful auscultation by an experienced clinician
- Grade II. A faint murmur that is clearly heard after only a few seconds auscultation
- Grade III. A murmur that is immediately audible as soon as auscultation begins and is heard over a reasonably large area
- Grade IV. An extremely loud murmur accompanied by a precordial thrill. The murmur becomes inaudible if the stethoscope is held with only light pressure on the chest
- Grade V. An extremely loud murmur accompanied by a precordial thrill. The murmur can still be heard when the stethoscope is held with only light pressure against the chest.

Grade I murmurs are not clinically significant whereas grade IV and V invariably are. The significance of grade II and III murmurs varies according to their cause. A system that grades on a six-grade basis is also used and differs only in a further subcategorization of moderately loud and loud murmurs.

The presence of a precordial thrill is determined by palpation over the point of maximal intensity of the murmur and palpation on the chest over other areas of the heart. A precordial thrill indicates that there is considerable energy generated by the turbulent flow and defines the intensity of the murmur in the top two grades in both grading systems.

Location and radiation
Location and radiation of a murmur is related to its areas of generation and transmission. The point of maximum intensity (PMI) is noted with reference to the areas of maximum audibility of the heart valves described earlier under the heading of examination of heart sounds. Low-intensity murmurs are generally restricted to the auscultatory area overlying their area of generation. The auscultatory areas of the heart and of the individual heart sounds have been described earlier in the section on arrhythmias. The vibrations associated with very loud murmurs may be transmitted to other auscultatory areas but generally they are most intense near the area of generation, as is any associated thrill. Murmurs and thrills can be restricted to local areas and it is essential to examine several auscultatory areas over both sides of the heart.

Character
Character is determined by change in intensity during the duration of a murmur and is defined as crescendo, crescendo-decrescendo, decrescendo or plateau. Murmurs may also be described according to their frequency characteristics by terms such as blowing, honking, musical and buzzing, but these interpretations are very subjective and often not repeatable between examiners. Blowing murmurs do not have a major frequency peak of harmonics and therefore do not have an easily identifiable pitch. In contrast, musical, honking and buzzing murmurs have a primary frequency and associated harmonics. Musical murmurs have a higher fundamental frequency (pitch) than honking or buzzing murmurs, whereas honking murmurs are shorter in duration than buzzing murmurs.

Interpretation
Following this examination the functional defect producing the murmur and the valve involved are determined from the characteristics of timing and duration, location and radiation, and also any secondary effects that may be present in arterial or venous pulse characteristics. The severity of the lesion is judged in part on the intensity of the murmur but also on the degree of cardiac insufficiency that is present. As a rule all pansystolic mitral and tricuspid murmurs, all holodiastolic murmurs, all right-sided murmurs and all murmurs with a palpable precordial thrill should be considered pathological. The cause of the lesion cannot be determined from auscultation but may be determined from the results of general clinical and special pathological examinations and by a knowledge and consideration of the common causes of valvular disease that involve the particular valve affected in the animal species being examined.

Functional (innocent) murmurs
Murmurs not associated with cardiac abnormality occur in all large-animal species, but particularly the horse and the lactating dairy cow. Those associated with turbulence produced during periods of high-velocity flow are often called functional murmurs or flow murmurs; those associated with turbulence resulting from decreased viscosity and increased flow are often called physiological murmurs.

Functional systolic ejection murmurs
are very common in young, fit horses and occur occasionally in cattle, sheep and pigs. In horses, they are heard best over the base of the heart, usually on the left side over the aortic valve region, in some horses on the right side, but not usually on both sides in the same horse. They are early to mid systolic murmurs of low intensity (grade 1-3), and are crescendo decrescendo or decrescendo in character. In horses they are usually more audible at heart rates slightly elevated above the resting rate. Occasionally in horses, an ejection murmur is audible over the pulmonary valve.

In cattle they are most common at the base of the heart on the left side. A systolic ejection murmur is very common over the left anterior heart base in lactating dairy cattle and this murmur is thought to be due to turbulence at the pulmonic valves. Auscultation of this murmur requires placement of the stethoscope directly over the pulmonic valve; this murmur is usually not auscultable when the heart is auscultated at the fourth to fifth intercostal space. Holosystolic murmurs (grade 1-3) are heard in some calves in the first 2-3 weeks of life. They are possibly associated with minor deformation of the atrioventricular valves by hematocysts at the edge of the valve leaflets, which are common in young calves.

An early diastolic murmur occurs in horses, most commonly in young Thoroughbreds and Standardbreds, and is believed to be due to vibrations associated with the rapid flow of blood into the heart in early diastole. It is a soft (grade 1-2), high-pitched, early diastolic murmur. When heard over the apex area it is probably a variation of the S3 sound.
A presystolic murmur of grade 1–2 intensity and rumbling sound is occasionally heard in horses and is probably a component of the atrial fourth heart sound.

Recumbent cattle commonly have a low intensity (grade 1–3) crescendo-decrescendo systolic murmur that is auscultated over the right side. It will disappear when the animal stands. A similar murmur occurs where there is ruminal distension and bloat.

In newborn calves and foals a systolic murmur is frequently audible over the base of the heart and it is believed to be due to a partial temporary patency of the closing ductus arteriosus. In newborn pigs a continuous murmur may be heard and this is often replaced by an early systolic murmur audible for the first week of life. Insufficiency of the right atrioventricular valve

Tricuspid valve insufficiency resulting from endocarditis is the most common acquired valvular lesion in cattle, pigs and sheep. Insufficiency may also result from dilatation of the valve annulus in chronic anemia and with cor pulmonale in conditions such as high altitude disease in cattle. Tricuspid regurgitation can also occur with general heart failure that follows left-sided failure. Because of the association with bacterial endocarditis, tricuspid insufficiency in cattle, pigs and sheep is usually indicative of significant cardiac disease or the presence of marked pulmonary hypertension. However, in horses, the murmur of tricuspid insufficiency may be present with little evidence of impaired performance.

There is a harsh holosystolic or pansystolic plateau-type murmur most audible over the tricuspid valve area. Loud murmurs project dorsally and to the cranial part of the thoracic cavity on both right and left sides. The murmur is usually accompanied by an exaggeration of the systolic component of the jugular pulse. Congestive heart failure, if it occurs, will be manifest in the greater circulation.

Insufficiency of the left atrioventricular valve

This is the second most common acquired valvular disease in horses, cattle and pigs. The insufficiency may result from endocarditis or rupture of the mitral valve chordae. There is a loud harsh holosystolic or pansystolic murmur that is most intense in the mitral area. The murmur transmits dorsally and in severe cases may also be heard on the right side. There is frequently marked accentuation of the occurrence of the third heart sound, which may be mistaken for the second sound. A late systolic crescendo murmur has also been associated with mitral insufficiency.

The pulse characters are unchanged until the stage of cardiac failure. Cases of mitral insufficiency may compensate at rest and may be only evidenced by decreased work tolerance. Failure, if it occurs, will be initially associated with left ventricular volume overload; however, in some cases the retrograde flow of blood through the mitral valve may lead to pulmonary hypertension and the additional occurrence of right-sided heart failure.

Acute-onset heart failure is usually associated with rupture of the valve chordae. In the horse, mitral insufficiency may predispose to atrial fibrillation.

Insufficiency of the aortic valve

This is the most common acquired valvular defect in horses. There is a loud holodiastolic murmur, frequently accompanied by a thrill caused by the reflux of blood from the aorta into the left ventricle during diastole. The murmur is generally audible over the left cardiac area and is most intense at the aortic valve area and radiates to the apex. It may modify the second heart sound or start immediately following. The murmur may be noisy or musical and the relative intensity varies from horse to horse. Frequently it is decrescendo in character but other variations in its intensity occur. Valvular insufficiency of a sufficient degree to have functional significance is accompanied by an arterial pulse of very large amplitude and high systolic and low diastolic blood pressures (water-hammer pulse). The pulse wave may be great enough to cause a visible pulse in small vessels and even in capillaries. Rarely this lesion is accompanied by a diastolic jugular pulse due to transmission of the impact of the reflex wave across the ventricular septum to the right side of the heart.

Stenosis of the aortic valve

There is a harsh systolic murmur, most audible high up over the base of the heart on the left side and posteriorly. The murmur replaces or modifies the first heart sound and is often crescendo-decrescendo in character. A systolic thrill may be palpable over the base of the heart and the cardiac impulse is increased as a result of ventricular hypertrophy. The stenosis has most functional significance when the pulse is abnormal, with a small amplitude rising slowly to a delayed peak reflecting the diminished left ventricular output. There may be signs of left-sided heart failure and this lesion may also be associated with syncope.

Stenosis and insufficiency of the pulmonary valve

Acquired lesions of this valve are rare in large animals. The auscultatory characteristics are similar to those produced by aortic valve lesions but there are no abnormalities of the arterial pulse. Pulmonary stenosis produces a distinct murmur at the third intercostal space on the left side of the chest but some cases of pulmonary stenosis in the horse have no murmur. Murmurs may also be audible anterior to the aortic valve area on the left side of the chest. Heart failure, if it occurs, is right-sided.

Stenosis of the right or left atrioventricular valves

Stenosis of either atrioventricular valve is uncommon. There is a diastolic murmur caused by passage of blood through a stenosed valve during diastolic filling and audible over the base of the heart on the relevant side. The severity of the lesion will govern the duration of the murmur but there is likely to be a presystolic accentuation due to atrial contraction. Right atrioventricular valve stenosis may be accompanied by accentuation of the atrial component of the jugular pulse. Some degree of mitral stenosis may occur in acquired lesions that manifest primarily as an insufficiency.

CLINICAL PATHOLOGY

Clinicopathological findings will reflect the changes caused by the primary disease and are significant only when there is endocarditis. Two-dimensional echocardiography, Doppler echocardiography and color flow Doppler echocardiography are the most valuable noninvasive methods for the examination of valvular disease and allow a detection of the defect, its nature and its severity. Echocardiography may detect regurgitant flow and flow through stenotic valves that is not detected by auscultation.

NECROPSY FINDINGS

Care is needed when the heart is opened to ensure that the valves can be viewed properly from both upper and lower aspects. Lesions of endocarditis may be visible or there may be perforations, distortion or thickening of the valves or breakage of the chordae tendineae. Endocardiosis in pigs is characterized by accumulation of glycosaminoglycans and hyaluronan and myofibroblast differentiation of fibroblasts.

DIFFERENTIAL DIAGNOSIS

Murmurs must be differentiated from pericardial and pleural friction sounds and from murmurs due to congenital defects with shunts.

TREATMENT

There is no specific treatment for valvular disease. Methods for the treatment of
congestive heart failure and endocarditis are discussed under those headings.

**REVIEW LITERATURE**

**REFERENCES**

**ENDOCARDITIS**

**Synopsis**

**Etiology** Bacterial, occasionally parasitic infection

**Epidemiology** History of ill-thrift, chronic illness, periodic milk drop, shifting lameness

**Clinical findings** Type of murmur depends on valves of species predilection. Embolic nephritis, arthritis, tenosynovitis, or myocarditis

**Clinical pathology** Blood culture

**Necropsy findings** Valvular lesions, often vegetative, maybe rupture of chordae tendineae. Embolic lesions in other organs

**Diagnosis** Murmur or persistent tachycardia with evidence of bacteremia, a positive blood culture. Can be confirmed by echocardiography

**Treatment** Antimicrobial agents based on culturing causative agent. Prolonged therapy required. Case fatality uniformly high in cases that have heart failure

**ETIOLOGY**

Most cases of endocarditis in farm animals are caused by bacterial infection but whether the infection gains entrance by direct adhesion to undamaged endocardium, or through minor discontinuities of the valvular surfaces, or by hematogenous spread through the capillaries at the base of the valve, is uncertain. A number of different organisms have been associated with this disease. The common infectious causes of endocarditis in animals are listed below.

**Cattle**

- Alpha-hemolytic streptococci
- *Arcanobacterium (Actinomyces or Corynebacterium)* pyogenes
- Micrococcus and *Staphylococcus* spp.
- *Pseudomonas* spp.
- Clostridium chauvoei (blackleg)
- Mycoplasma mycoides
- *Erysipelothrix rhusiopathiae* (insidiosa) (rare).

**Horses**

- *Actinobacillus equuli*
- *Streptococcus* spp., including *Streptococcus equi* and *Streptococcus zooepidemicus*
- *Pasteurella/Actinobacillus* spp.
- *Pseudomonas* spp.
- Migrating *Streptococcus* spp. *lavae*.

**Pigs and sheep**

- *Erysipelothrix rhusiopathiae* (insidiosa)
- *Streptococcus* spp. including *Streptococcus equisimilis*, *Streptococcus dysgalactiae*, *Streptococcus suis*
- *Escherichia coli*
- *A. pyogenes*.

**EPIDEMIOLOGY**

There is limited information on the epidemiology of the endocarditis. (See Epidemiology, valvular disease.)

Chronic bacteremia predisposes to endocarditis. There may be a history of an ongoing septic process such as mastitis, metritis, foot abscess or traumatic reticular peritonitis, or of a procedure, such as the use of an indwelling intravenous catheter, that might lead to bacteremia. Commonly there is a history suggestive of low-grade infection. In cattle, ill-thrift with periodic, dramatic but temporary fall in milk production is a common history. The animals often have a lower body condition than expected for their stage of production and there is frequently a history of intermittent lameness. Horses may present with similar suggestive histories, including shifting leg lameness, intermittent joint distension, coughing, seizures, jugular vein thrombosis, colic, diarrhea, poor growth and umbilical infection. In sows it is common for agalactia to develop in the first 2–3 weeks after farrowing, followed by a loss of weight, intolerance to exercise and dyspnea at rest.

**PATHOGENESIS**

Endocarditis may arise from implantation of bacteria onto the endocardium from the bloodstream or by bacterial embolism of the valve capillaries. Endocarditis is predisposed by trauma to the endocardial surface exposing collagen and leading to binding of platelets, activation of the extrinsic coagulation cascade with deposition of fibrin and the formation of sterile platelet–fibrin deposits.

Endothelial damage may occur along the lines of closure of valves in association with turbulent flow and also can occur for the same reason on areas of the mural endocardium. These areas are subsequently colonized by circulating bacteria and the organisms grow in these areas ensnared in a tight, avascular network of fibrin and platelets and with further serial deposition of platelets and fibrin. This is the mechanism of endocarditis that occurs secondary to turbulent flow in congenital heart disease and of that produced by trauma such as cardiac catheterization. Myocardial disease may lead to edema of the valves, which may also predispose to endothelial damage.

Endocarditis in large animals occurs most commonly secondary to a chronic infection at some distant site and a persistent bacteremia without predisposing lesions in the heart. Certain organisms have the ability to directly adhere to endocardium and it is probable that this is the major pathogenic factor.

The major clinical abnormalities associated with endocarditis result from the effect of endocarditis on heart function and from the effects of embolic showering of microorganisms, which can lead to infarction or infection at other sites in the body. The valvular lesions may be vegetative in the early stages of the disease or, more often, there may be fibrosis and shrinking, distortion and thickening of the valve cusps. Both interfere with valve function, leading to cardiac insufficiency and possibly cardiac failure. The functional defect produced by valvular endocarditis is usually, but not invariably, valvular insufficiency. Infected emboli most commonly produce pulmonary embolism with miliary pulmonary abscessation, or infection or abscesses in
other organs, including myocardium, kidneys and joints.

Valve predilection
In cattle, endocarditis occurs most commonly on the right atrioventricular (tricuspid) valve. The left atrioventricular (mitral) valve is the second valve of predilection, and bilateral involvement of the atrioventricular valves is not uncommon. In the horse the most common site of infection is the aortic valve, with the left and the right atrioventricular valves being the second and the third valve sites of predilection. Endocarditis of the pulmonary valve is uncommon, but is recorded. The atrioventricular valves are the predilection sites in sheep and swine.

**CLINICAL FINDINGS**

**Cardiac signs**
The important finding is a murmur on auscultation or a thrill on palpation of the cardiac area. Details of the specific findings for individual valve abnormalities can be found in the preceding section on valvular disease. A major problem with diagnosis based on the presence of murmurs is that they are not always present or detected in cases of endocarditis, particularly with right sided lesions. Persistent tachycardia should be regarded as the most consistent clinical sign in endocarditis.

**Emboli**
Chronic bacteraemia and embolic showering of microorganisms results in signs referable to infection and infarction at other sites in the body. There is a constant moderate, fluctuating fever and secondary involvement of other organs may cause the appearance of signs of peripheral lymphadenitis, embolic pneumonia, nephritis, arthritis, tenosynovitis or myocarditis. There is usually much loss of condition, pallor of mucosae and an increase in heart rate.

**Clinical course**
The clinical course in endocarditis may be as long as several weeks or months, or animals may drop dead without premonitory signs. Endocarditis is also a cause of acute heart failure and sudden death in sows. Because sows are confined with minimal exercise during much of the production cycle, the presence of cardiac insufficiency from chronic endocarditis can be masked and sows with chronic endocarditis may have acute heart failure and die at times of intense exercise, such as mating or during movement to other housing.

**Rupture of the chordae tendinae**
Rupture of the chordae tendinae of the mitral valve in horses may be preceded by endocarditis or may occur spontaneously and occurs in both adults and foals. It is manifested by sudden onset of acute heart failure in horses apparently previously healthy or, when a complication of a pre-existing endocarditis, as a sudden onset complication of the disease or a cause of death. There are signs of acute left failure and there is usually a prominent third heart sound. The rupture may involve the chordae of any of the cusps of the valve. Rupture of the medial cusp of the aortic valve to produce acute left heart failure and rupture of the pulmonary valve producing right heart failure can also occur.

**Cardiography**

Electrocardiographic findings suggestive of endocarditis are sinus tachycardia and decreased QRS amplitudes in a base-apex lead; ectopic foci may also be present.

Echocardiographic findings suggestive of endocarditis are hypoechoic and echogenic masses, irregular thickening of valves and rupture of the chordae tendinae.

**CLINICAL PATHOLOGY**

A nonregenerative anemia, leukocytosis, neutrophilia, hyperfibrinogenemia and hyperglobulinemia are common but not specific for endocarditis. In chronic cases, where the lesions are due largely to scarring of the valves, hematological findings may be normal. Hypergammaglobulinemia is the most common and consistent finding and an indication of chronic bacterial infection. Where there is passive hepatic congestion there may be an increase in serum alkaline phosphatase and gamma-glutamyltransferase activity. Repeated examination of the urine may reveal transient episodes of proteinuria and the shedding of bacteria associated with renal embolization and infarction.

**Blood cultures** should be attempted. The avoidance of skin contamination is important and the site should be adequately prepared by initial skin cleansing with 70% alcohol followed by 1% povidone-iodine applied in a circular pattern around the intended venepuncture site. A contact time of at least 2 minutes should be allowed before obtaining blood for culturing. The ratio of blood to broth culture medium should be 1:10–120, and the broth should be incubated at 37°C for 24 hours before being examined for the presence of turbidity and plated on to traditional blood agar plates. Blood culture is frequently negative and it is recommended that three samples be obtained from separate venepuncture sites during a 1-hour period. Sampling at the start of a fever is preferred but clearly impossible; however in animals with a more constant bacteremia, repeat culturing without regard to fever is successful. Determination of the susceptibility of the organism to antimicrobial agents may aid in treatment.

**NECROPSY FINDINGS**
The lesions are termed vegetative when they are large and cauliflower-like and verrucose when they are small and wart-like. The former are present on the valves in most fatal cases. In the later stages the valves are shrunk, distorted and often thickened along the edges. This stage of recovery is rare in farm animals but may be observed in the semilunar valves in horses. Spontaneous healing is rare and in most cases treatment is commenced at too late a stage.

Embolic lesions may be present in any other organ. Culture of the valvular lesions should be undertaken but in many cases no growth is obtained. The examination of direct smears should always be undertaken.

**DIFFERENTIAL DIAGNOSIS**

- Pericarditis
- Bovine disease (cattle)
- Cardiac lymphosarcoma

**TREATMENT**

Treatment is not highly successful because of the difficulty in controlling the infection. The thickness of the lesions prevents adequate penetration of antimicrobial agents and unless the susceptibility of the causative organism is known a range of antibacterial drugs may have to be tried. For this reason there should be repeated attempts at blood culture until the causative organism is cultured in order to allow drug selection on the basis of susceptibility testing. The choice of antimicrobial agent should be one that allows high concentrations in serum relative to the minimal bactericidal concentration, that has minimal side effects over a prolonged period of administration and has a prolonged half-life.

In the absence of a positive culture the types of organism commonly isolated in cattle suggest the use of penicillin, possibly combined with gentamicin or the use of a potentiated sulfonamide. The variety of causative organisms in horses recommends the use of broad-spectrum antibacterial treatment.

**Duration of treatment** needs to be prolonged. It is difficult to judge the duration of therapy required. A fall in temperature can be taken as an indication that infection is being brought under...
control, but treatment needs to be
continued if there is to be success in
therapy.\textsuperscript{3,10,14,15} A period of continual
treatment for 4 months with periodic
treatment continuing for 14 months in a
cow has been recorded.\textsuperscript{2}

\textbf{Relapse} is common. Treatment is
expensive and in food animals must be
extra-label and is probably uneconomic
except for particularly valuable animals.
Consequently the treatment of endo-
carditis should be approached with
reservation. \textbf{Case fatality} is high if signs
of congestive heart failure are present.

The \textbf{sequel} of embolic lesions in other
organs and permanent distortion of
valves resulting in valvular insufficiency
also militate against a satisfactory out-
come. The use of parenteral anti-
coagulants, as used in humans to prevent
further deposition of material on vegeta-
tive lesions and to limit embolic disease,
has questionable value\textsuperscript{21} and requires
monitoring that is not usually available in
veterinary practice.

\textbf{Diseases of the pericardium}

\textbf{PERICARDITIS}

\textbf{Synopsis}

\textbf{Etiology} Traumatic, extension from other
infection, as component of infections
causes polymyositis, or idiopathic

\textbf{Epidemiology} Poorly defined other than
for traumatic pericarditis in cattle

\textbf{Clinical findings} Friction sound initially,
followed by muffling of the heart sounds,
venous congestion, decreased pulse
pressure and congestive heart failure

\textbf{Clinical pathology} Pericarditis, echocardiography, radiography

\textbf{Necropsy findings} Inflammation, fibrin
and fluid, in pericardial sac. Fibrous
pericarditis.

\textbf{Diagnostic confirmation} Triad of
muffling of the heart sounds, venous
congestion, decreased pulse pressure.
Pericarditis, echocardiography

\textbf{Treatment} Antimicrobials and drainage.
Poor prognosis and supportive treatment

\textbf{ETIOLOGY}

Pericarditis is not common but presents in
three general forms; effusive, fibrinous
and constrictive, although combinations
of one or more of the three forms can
occur. \textbf{Effusive pericarditis} is charac-
terized by the accumulation of a protein-
rich fluid within the pericardial sac.
Subsequent fibrin deposition can lead to
fibrinous pericarditis, and if fibrin
within the pericardial sac matures to
fibrous tissue and fibrosis of the peri-
cardium or epicardium then \textbf{constrictive
pericarditis} will result.\textsuperscript{1}

\textbf{Traumatic pericarditis}, perforation of the pericar-
dial sac by an infected foreign body,
occurs commonly only in cattle. Traumatic
pericarditis is also recorded in the horse\textsuperscript{2}
and in a lamb.\textsuperscript{3} Localization of a
blood-borne infection occurs sporadically in
many diseases. Direct extension of infec-
tion from pleurisy or myocarditis may also
occur in all animals but the clinical signs
of pericarditis in such cases are usually
dominated by those of the primary
disease.

In most cases of pericarditis in \textbf{horses}
no causative agent is isolated.\textsuperscript{1} There
is commonly a history of upper or lower
respiratory tract disease. Most cases are
fibrinous or septic\textsuperscript{4,5} but an effusive nons-
septice form is also described and has been
called \textbf{idiopathic effusive pericarditis}.\textsuperscript{6}

\textbf{Pericarditis} in horses occurs predominantly
in adults. Idiopathic effusive pericarditis
has been diagnosed in two dairy cows.\textsuperscript{7}

\textbf{Cattle}

- Mannheimia hemolytica
- Black disease – if patients survive
more than 24 hours
- Sporadic bovine encephalomyelitis
- Haemophilus spp., including
- Histophilus somni
- Tuberculosis
- Pseudomonas aeruginosa
- Mycoplasma spp.
- Klebsiella pneumoniae
- Actinobacillus suis
- Idiopathic effusive (nonseptic)
pericarditis.

\textbf{Horses}

- Streptococcus spp., including \textit{S. equi},
- \textit{S. zooepidemicus} and \textit{S. faecalis}
- Tuberculosis
- Corynebacterium pseudotuberculosis
- Actinobacillus equi
- In association with EHV-1 infection
- Idiopathic effusive (nonseptic)
pericarditis.

\textbf{Sheep and goats}

- Pasteurellosis
- Staphylococcus aureus
- Mycoplasma spp.

\textbf{Pigs}

- Pasteurellosis
- Mycoplasma spp. especially
Mycoplasma mycormis
- Haemophilus spp. – Glasser’s disease
and pleuropernionia
- Streptococcus spp.

\textbf{PATHOGENESIS}

In the \textbf{early stages}, inflammation of the pericardium is accompanied by hyperemia
and the deposition of fibrinous exudate,
which produces a friction sound when the
pericardium and epicardium rub together
during cardiac movement. As effusion
develops the inflamed surfaces are
separated, the friction sound is replaced
by muffling of the heart sounds, and the
accumulated fluid compresses the atria
and right ventricle, preventing their
complete filling. Congestive heart failure
follows. A severe toxemia is usually present
in supplicative pericarditis because of the
toxins produced by the bacteria in the
pericardial sac. Gas will occur along with
fluid in the sac if gas-producing bacteria
are present. If sufficient gas is present, the
classical washing machine sound of fluid
splashing with each heart beat will be
asculpted. This is not as commonly
heard in clinical cases as muffling of the
heart sounds.

In the \textbf{recovery stage} of nonsuppu-
lative pericarditis the fluid is reabsorbed
and adhesions form between the
pericardium and epicardium to cause an
adhesive pericarditis, but the adhesions
are usually not sufficiently strong to
impair cardiac movement.

\textbf{In suppurative pericarditis} the ad-
hesions that form become organized,
starting on day 4–6,\textsuperscript{8} and may cause
complete attachment of the pericardium to the epicardium, or this may occur only in patches to leave some loculi which are filled with serous fluid. In either case restriction of cardiac movement will probably be followed by the appearance of congestive heart failure.

**CLINICAL FINDINGS**

In the early stages there is pain, avoidance of movement, abduction of the elbows, arching of the back and shallow, abdominal respiration. Pain is evidenced on percussion or firm palpation over the cardiac area of the chest wall, and the animal lies down carefully. A pericardial friction sound is detectable on auscultation of the cardiac area. The temperature is elevated to 39.5–41°C (103–106°F) and the pulse rate is increased. Associated signs of pleuritis, pneumonia and peritonitis may be present.

In most cases of pericarditis caused by traumatic reticuloperitonitis, hematogenous infection or spread from pleuritis, the second stage of effusion is manifested by muffling of the heart sounds, decreased palpability of the apex beat and an increase in the area of cardiac dullness with decreased amplitude of the peripheral pulse. If gas is present in the pericardial sac each cardiac cycle may be accompanied by splashing sounds. Signs of congestive heart failure become evident. Fever is present, the heart rate is markedly increased and toxemia is severe, although this varies with the types of bacteria present. This is the most dangerous period and affected animals usually die of congestive heart failure, or of toxemia, in 1–3 weeks. Those that survive pass through a long period of chronic ill health during which the toxemia subsides relatively quickly but congestive heart failure diminishes slowly. In this stage of chronic pericarditis additional signs of myocarditis, particularly irregularity, may appear. The heart sounds become less muffled and fluid sounds disappear altogether or persist in restricted areas. Complete recovery is not common.

In the horse, both the idiopathic effusive and the septic forms of pericarditis present with marked muffling of the heart sounds, tachycardia, distension of the jugular veins and subcutaneous edema of the ventral body wall. A nonseptic pleural effusion is also commonly present in cases of septic pericarditis in the horse but not in idiopathic effusive pericarditis.

**CLINICAL PATHOLOGY**

A marked leukocytosis and neutrophilia, as well as hyperglobulinemia, are usually present in traumatic pericarditis because this has many of the characteristics of a large internal abscess. In the other forms of pericarditis changes in the blood depend upon the other lesions present and on the causative agent. In the stage in which effusion occurs a sample of fluid may be aspirated from the pericardial sac and submitted for bacteriological examination. The technique is not without danger, as infection may be spread to the pleural cavity.

Pericardial fluid can also be examined cytologically but usually the smell (reminiscent of retained placenta and toxic metritis in cattle) is sufficiently diagnostic in cattle with traumatic pericarditis. In septic pericarditis the fluid represents an inflammatory response, whereas in idiopathic effusive pericarditis in horses there are very few cells in the sediment.

Mean right ventricular diastolic and intrapericardial fluid pressures are increased in a corresponding manner in cows with clinical signs of right-sided heart failure. Cattle with muffled heart sounds and a large pericardial fluid volume also have a decrease in cardiac output to approximately two-thirds of normal values.

Electrocardiography can aid in diagnosis. Electrocardiographic changes include sinus tachycardia and, in animals with right-sided heart failure and hydrothorax, diminished amplitude of the QRS complex. Contrary to popular belief, hydropericardium in the absence of hydrothorax leads to an increase, and not a decrease, in QRS amplitude. Moreover, removal of large volumes of pericardial fluid does not usually result in an immediate change in QRS amplitude. Also contrary to popular belief, electrical alternans is not commonly present in dogs and humans with pericardial effusion and if present, occurs only within a narrow range of heart rates. The prevalence of electrical alternans is unknown in large animals with pericardial effusion but is suspected to be extremely low because the pericardium and heart are much more fixed in position within the thorax.

Radiography may be of diagnostic value, with six of seven cows having a gas–fluid interface present on standing lateral thoracic radiographs. Radiography has the additional benefit of potentially identifying the location of the penetrating wire; this information would assist surgical removal of the wire via a rumenotomy. Radiography may also aid in the clinical differentiation of pericardial effusion from pleural effusion.

Echocardiography is the most valuable diagnostic procedure and will show the presence of fluid in the pericardial sac. Echocardiography usually permits differentiation of effusive and fibrous pericarditis.

**NECROPSY FINDINGS**

In the early stages there is hyperemia of the pericardial lining and a deposit of fibrin. When effusion occurs there is an accumulation of turbid fluid and tags of fibrin are present on the greatly thickened epicardium and pericardium. Gas may also be present and the fluid may have a putrid odor. When the pericarditis has reached a chronic stage the pericardium is adherent to the epicardium over a greater or lesser part of the cardiac surface. Loculi containing serous fluid often remain. Embolic abscesses may be present in other organs. Lesions typical of the specific causative diseases listed above are described under their specific headings.

**DIFFERENTIAL DIAGNOSIS**

- Pleuritis
- Cardiac valvular disease
- Mediastinal abscess
- Hydropericardium occurs in congestive heart failure, mulberry heart disease of pigs, herzotid of pigs, gossypol poisoning, clostridial intoxications of sheep and lymphomatosis

**TREATMENT**

Antibacterial treatment of the specific infection should be undertaken if possible on the basis of susceptibility on organisms cultured from the pericardial fluid. Where the inciting agent cannot be grown a broad-spectrum antibiotic or a combination to give a broad spectrum is used. A combination of penicillin and gentamycin is common and provides cover of the likely organisms associated with this infection. Pericardiocentesis, copious lavage with warmed 0.9% NaCl solution, and drainage should be conducted as required to relieve the fluid pressure in the pericardial sac, decrease the transmural pressure gradient across the atrial and ventricular walls and caudal and cranial vena cava, and thereby facilitate diastolic filling. Pericardiocentesis should be performed under ultrasonographic guidance and with electrocardiographic monitoring.

The prognosis varies with the etiological agent but it is generally grave in cases of septic pericarditis in horses mainly because the stage of effusion is followed by one of fibrosis and constricitive pericarditis. Success in treatment of a series of six cases of septic pericarditis in the horse is recorded with the use of indwelling pericardial drains to allow twice-daily lavage and drainage and the instillation of antibiotics directly into the pericardial sac. This allows high concentrations of antimicrobial agents and the twice-daily infusion of 1–2 L of fluid may
help prevent the development of constrictive pericarditis. In cattle thoracotomy and pericardiectomy are used to establish drainage or to allow marsupialization of the pericardium to the body wall.\textsuperscript{18} Low treatment success rates are generally reported for the disease in cattle with or without surgical drainage,\textsuperscript{16,19} and it is likely that cases that responded to fifth rib resection and pericardial marsupialization would have responded to pericardial drainage and intrapericardial lavage and antimicrobial administration.

There is a more favorable prognosis for the treatment of idiopathic effusive pericarditis in horses and cattle with aggressive therapy and the use of pericardiocentesis, pericardial lavage and corticosteroid or NSAIDs is an effective therapy.\textsuperscript{7,12,14}

CONGENITAL CARDIAC DEFECTS

**ETIOLOGY**

An increasing number of clinical reports on congenital cardiovascular defects are appearing in the veterinary literature. However, their general importance is low.

The cause of congenital cardiac defects is unknown, but it is assumed they result from injury during development or from single recessive genes or polygenic sets that have lesion-specific effects on cardiac development.\textsuperscript{1} Ventricular septal defects have been observed in twin cattle.\textsuperscript{2} Heritable ventricular septal defect is recorded in miniature pigs\textsuperscript{3} and suspected in cattle.\textsuperscript{4}

**EPIDEMIOLOGY**

Congenital cardiac anomalies occur in all species but are not common in any one of them. The prevalence is probably highest in cattle and lowest in horses.\textsuperscript{5}

**Cattle**

The relative frequency of individual cardiac defects in 36 calves at postmortem examination in one study\textsuperscript{6} was:

- Ventricular septal defect - 14%
- Ectopic heart - 13%
- Right ventricular hypoplasia - 13%
- Left ventricular hypoplasia - 13%
- Dextroverted aorta - 10%
- Valvar hematomas - 9%
- Patent ductus arteriosus - 8%
- Patent foramen ovale - 6%
- Endocardial fibroelastosis - 4%
- Common aortic trunk - 4%
- Other cardiac defects - 10%.

The animals were neonatal calves and the relative frequencies are biased towards defects that are incompatible with longer life. In general, ventricular septal defect is the most common cardiac defect in cattle.

**Sheep**

In a large series of necropsy examinations on lambs,\textsuperscript{7} 3.1% had cardiac anomalies, of which approximately 90% were ventricular septal defects.

**Pigs**

The relative frequency of congenital cardiac malformations in pigs\textsuperscript{8} has been reported as:

- Dysplasia of the tricuspid valve - 34%
- Atrial septal defect - 25%
- Subaortic stenosis - 18%
- Ventricular septal defect - 9%
- Persistent common arterial trunk - 9%
- Other defects - 10%.

**Horses**

A review of 82 publications on congenital cardiac defects in horses showed the following prevalence in the total cases:\textsuperscript{9}

- Ventricular septal defect - 28%
- Tetralogy of Fallot - 16%
- Truncus arteriosus - 8.5%
- Aortic, pulmonary or mitral valve abnormalities - 13.2%
- Tricuspid atresia - 14.6%
- Abnormality of the aorta - 4.8%
- Patent ductus arteriosus - 3.7%
- Atrial septal defects - 1.2%

Other lesions account for the remainder.

**PATHOGENESIS**

Congenital cardiac defects may result in a pressure load or a volume (flow) load in one or more chambers of the heart. In general the left ventricle can tolerate a pressure load better than the right ventricle and the right ventricle can tolerate a volume load better than the left ventricle. The heart may compensate for the increase in load with minor loss in cardiac reserve or the defects may lead to cardiac failure.

**Shunts**

The mixing of oxygenated and venous blood due to the presence of an anatomic abnormality that allows a shunt of blood from the pulmonary circulation to the systemic circulation in the face of high pulmonary vascular resistance is an important factor in the pathogenesis of the clinical signs of some congenital cardiac defects. The resulting anoxic anoxia causes severe dyspnea, and cyanosis may be marked if the right-to-left shunt is large. There is a notable absence of fever and toxemia if intercurrent disease does not develop. Cardiac enlargement is usually detectable if the animal survives past the first week of life.

**Age at manifestation**

Animals with some congenital cardiac defects can survive to maturity and be productive and perform adequately. Acute heart failure or chronic (congestive) heart failure may occur when the animals are subjected to a physical stress such as the first pregnancy or activity on the range. The primary appearance of signs of cardiac disease when an animal is 2–3 years of age should not eliminate congenital defects from consideration.

**CLINICAL FINDINGS**

A general description of the more common defects is given below. Some of the defects described in this section are actually defects of the vascular system but are described here for convenience. Diagnosis can be confirmed by the detection of a pressure differential across valves, the detection of shunts by dye dilution and serial blood gas analysis, and by angiocardiography. Echocardiography has developed as an important aid to diagnosis.\textsuperscript{9}

**Ectopic heart**

An abnormal position of the heart outside the thoracic cavity is most common in
cattle, the displacement usually being to the lower cervical region. The heart is easily seen and palpated and there is an accompanying divergence of the first ribs and a ventrodorsal compression of the sternum, giving the appearance of absence of the brisket. Affected animals may survive for periods of years, as they also may with an abdominal displacement, but those with a displacement through a defective sternum or ribs rarely survive for more than a few days.

**Patent foramen ovale**

This defect of the atrial septum is reasonably common in cattle, usually causes no clinical signs if present as an isolated defect and is detected incidentally at necropsy. Ostium secundum defects are also common in cattle. Large defects may allow a shunt in both directions. Relative resistance to outflow from the atria is greater in the left than the right and the shunt, if it occurs, is from left to right. This induces a moderate flow load on the right side of the heart, which is well tolerated. Large flows will generally increase pulmonary vascular resistance and result in moderate right ventricular and right atrial hypertrophy. The increase in outflow resistance from the right atrium results in a decreased flow across the shunt and control of the effects of the defect. Atrial septal defects are of much greater significance when they are present with other cardiac defects and it is extremely rare for an atrial septal defect alone to cause clinical signs of circulatory failure. If these result in a severe right ventricular hypertrophy the shunt may reverse from right to left and cyanosis will occur.

**Ventricular septal defects**

These are one of the most common congenital cardiac defects in sheep, cattle and horses. They are almost invariably subaortic defects occurring high in the septum at the pars membranacea. In the absence of other defects their presence results in the shunting of blood from the left to the right ventricle, producing a volume load on the left ventricle and left atrium.

On auscultation there is a loud blowing pansystolic murmur audible on both sides of the chest. It is usually audible over a large area on both sides but most intense at the left fourth intercostal and the right third intercostal space and more intense on the right than the left side. The murmur in this defect is one of the loudest and most obvious murmurs encountered. It does not modify the heart sounds, which are usually increased in intensity. A precordial thrill is frequently palpable on both the left and the right side.

The outcome is determined by the magnitude of the shunt and the degree of resistance to flow from the right ventricle as determined by pulmonary vascular resistance. With large defects the shunt of blood can be considerable and the animal may die at birth or show clinical signs at a few weeks to a few months of age. The major presenting signs during this period are of left-sided heart failure with lassitude, failure to grow well and dyspnea with moderate exercise. The shunt may be less severe and allow an apparently normal existence until maturity, when left-sided or right-sided failure can occur, or cause no apparent problem during life and be detected incidentally on necropsy or abattoir examination. Horses with this defect have raced successfully and dairy cows have had many productive lactations.

**Complications**

An increase in pulmonary vascular resistance occurs as the result of increased pulmonary blood flow. In cattle, this increase may be sufficient to cause reversal of the shunt, and cyanosis develops. This syndrome, sometimes referred to as an Eisenmenger complex, develops in young calves but also in mature animals between 1 and 3 years of age and should always be suspected where there is a sudden onset of cyanosis and exercise intolerance in an animal of this age.

The turbulence associated with flow across the defect may produce secondary changes in the valves located close to the defect, which may complicate the clinical picture. Cattle are prone to develop endocarditis in the region of the septal cusp of the right atrioventricular valve. In horses, endocarditis more commonly involves the medial cusp of the aortic valve.

Other complications are prolapse of the cusps into the septal defect due to lack of aortic root support with the development of aortic regurgitation. Rupture of the valve may occur to produce a severe additional flow load on the left ventricle, with rapid onset of acute left heart failure and death.

Ventricular septal defects may occur in association with other congenital cardiac or vascular defects, and the clinical findings are varied.

**Prognosis**

There is no practical correction for ventricular septal defects in large animals. It should be emphasized that small defects can produce dramatic auscultatory findings and, unless signs of cardiac insufficiency are present, care should be taken in giving an unfavorable prognosis in pleasure or breeding animals. Pleasure animals with this defect should never be ridden but it is possible for them to live a reasonable lifespan and to breed. Food animals can be sent for early slaughter.

There is insufficient information on the advisability of breeding animals that have this defect. An inherited predisposition has been suspected in Hereford cattle, and chromosomal abnormalities have been demonstrated in association with this defect in cattle. Ventricular septal defects have high prevalence in calves and lambs with microphthalmia.

**Tetralogy of Fallot**

This is almost always a lethal defect in farm animals. The tetralogy consists of three primary abnormalities (ventricular septal defect, pulmonary stenosis, and dextroposition of the aorta so that it overrides both ventricles) and secondary right ventricular hypertrophy. The marked increase in resistance to outflow into the pulmonary artery results in a shunt of blood from the right to left with the major outflow of blood through the aorta. The condition presents with clinical signs very early in life, frequently results in death at, or shortly following birth and has been reported predominantly in foals and calves. Occasionally, affected animals may live for longer periods and cases are recorded in mature animals.

Affected animals show lassitude and dyspnea after minor exertion such as suckling, with the clinical signs resulting primarily from systemic hypoxemia. Cyanosis may or may not be present, depending upon the degree of pulmonary stenosis, but is usually prominent, especially following exercise. On auscultation a murmur and sometimes a thrill is present and most intense in the left third or fourth intercostal space.

Other cardiac defects that result in cyanosis as a prominent sign occur when there is right-to-left shunting of blood through a patent foramen ovale, a patent ductus arteriosus or ventricular or atrial septal defects as a result of tricuspid atresia or pulmonary atresia. Right-to-left shunting through these defects is rare and, if present, is usually a terminal event.

Tetralogy of Fallot should be differentiated from an even rarer condition, double outlet right ventricle; the latter is characterized by having both the aorta and pulmonary artery arise from a distinct conus originating from the morphologic right ventricle and from which no fibrous continuity with the atrioventricular valves can be demonstrated. Double outlet right ventricle has been diagnosed in three calves and a foal, with clinical signs similar to tetralogy of Fallot.

**Patent ductus arteriosus**

This defect results from a failure of closure of the ductus arteriosus following birth and is probably the second most common circulatory anomaly to affect newborn ruminants. This anomaly is characterized by a communication between the aorta and the pulmonary artery. This communication may close within hours or days of birth, or remain patent throughout life. In the latter case, the shunt is most often directed from the pulmonary artery to the aorta and is usually of low volume. In a few cases, the shunt may be of larger magnitude.

The outcome is determined by the magnitude of the shunt and the degree of resistance to flow from the right ventricle as determined by pulmonary vascular resistance. With large defects the shunt of blood can be considerable and the animal may die at birth or show clinical signs at a few weeks to a few months of age. The major presenting signs during this period are of left-sided heart failure with lassitude, failure to grow well and dyspnea with moderate exercise. The shunt may be less severe and allow an apparently normal existence until maturity, when left-sided or right-sided failure can occur, or cause no apparent problem during life and be detected incidentally on necropsy or abattoir examination. Horses with this defect have raced successfully and dairy cows have had many productive lactations.
defect in horses after ventricular septal defect. There is some controversy over the period of time involved in normal closure in large animals. Clinically, murmurs associated with a patent ductus arteriosus are frequently heard during the first day after birth in normal foals and may persist for periods of up to 5 days. Physiological studies in foals suggest that closure occurs before 24 hours after birth. Patent ductus arteriosus is not a common clinical cardiac defect in older animals, but can occur. The ductus arteriosus closes within minutes of birth in calves.

Patent ductus arteriosus produces a loud continuous murmur associated with the left-to-right shunting of blood from the aorta to the pulmonary artery. The intensity of the murmur waxes and wanes with each cycle because of the effects of normal pressure changes on blood flow, giving rise to the name of 'machinery murmur'. The systolic component of the murmur is very loud and usually audible over most of the cardiac auscultatory area, but the diastolic component is much softer and confined to the base of the heart. The pulse is large in amplitude but has a low diastolic pressure. Surgical correction is possible.

**Coarctation of the aorta**

Constriction of the aorta at the site of entrance of the ductus arteriosus causes a syndrome similar to that of stenosis of the aortic semilunar valves; there is a systolic murmur and a slow-rising pulse of small amplitude.

**Persistence of the right aortic arch**

Persistence of the right fourth aortic arch causes constriction of the esophagus with dysphagia and regurgitation. The aorta is situated to the right of the esophagus and trachea and the ligamentum arteriosum in its connection to the pulmonary artery encloses the esophagus in a vascular ring and compresses it against the trachea. Clinical signs are usually evident soon after birth and consist primarily of regurgitation of milk from the mouth and nostrils after sucking, but survival until 5 years of age has been recorded in a bull that showed chronic bovine and visible esophageal dilation. Resistance to the passage of a stomach tube is encountered just behind the first rib and the diagnosis can be confirmed by radiological examination following a barium swallow. Medical treatment is concerned with the control of aspiration pneumonia, but the correction of the defect is surgical.

**Persistent truncus arteriosus**

This defect and other defects of the outflow vessels, including pulmonary and aortic hypoplasia and conal absence of the aortic arch, have been recorded in animals but their prevalence is low.

**Fibroelastosis**

Congenital fibroelastosis has been observed in calves and pigs. The endocardium is converted into a thick fibroelast coat and, although the wall of the left ventricle is hypertrophied, the capacity of the ventricle is reduced. The aortic valves may be thickened and irregular and obviously stenosed. The syndrome is one of congestive heart failure. The defect may cause no clinical abnormality until the animal is mature.

**Subvalvular aortic stenosis**

Stenosis of the aorta at or just below the point of attachment of the aortic semilunar valves has been recorded as a common, possibly heritable, defect in pigs but its differentiation from other causes of heart failure is difficult. Clinically affected animals may die suddenly with asphyxia, dyspnea and foaming at the mouth and nostrils, or after a long period of ill-health with recurrent attacks of dyspnea. In the acute form death may occur after exercise or be unassociated with exertion.

**Parachute left atrioventricular valve**

This is an extremely rare congenital anomaly defined by the presence of a single papillary muscle that receives all chordae tendineae from the left atri­ventricular valve. An 8-month old colt with a loud left-sided holosystolic murmur was diagnosed with this condition using echocardiography.

**Anomalous origin of coronary arteries**

Either or both coronary arteries may originate from the pulmonary artery instead of the aorta. The resulting anoxia causes myocardial weakness in the ventricle of the affected side. Congestive heart failure usually follows. Congenital deformities of the coronary arteries have been recorded in cattle and pigs.

---

**REFERENCES**

---

**Cardiac neoplasia**

Primary neoplasia of the heart is exceedingly rare and cardiac disease secondary to metastatic neoplasms occurs infrequently. Aortic body adenoma, cardiac fibrosarcoma and pericardial mesothelioma are reported. Lymphosarcoma is probably the most common metastatic tumor in both cattle and horses but cardiac involvement by melanoma, hemangiosarcoma, testicular embryonal carcinoma, squamous cell carcinoma, lipoma and other tumors is also recorded. Angiomas, benign vasosformative tumors, can occur in the heart and are recorded as obstructing blood flow and producing heart failure in a young calf.

**REFERENCES**

**Diseases of the blood vessels**

**Arterial thrombosis and embolism**

**Synopsis**

**Etiology**

Arteritis leading to thrombus formation causes ischemia of the tissues supplied by the affected artery.

**Clinical findings**

Reduced function or ischemic necrosis vary with the site of the obstruction. Aortic–iliac thrombosis manifest with lameness, muscular weakness, decreased pulse amplitude in affected leg.

**Clinical pathology**

Leukocytosis, hyperfibrinogenemia, elevated serum concentrations of muscle enzymes in some cases. Ultrasound more sensitive for diagnosis than rectal palpation.

**Necropsy findings**

Thrombosis and embolic lesions, muscle ischemia and necrosis.

**Diagnostic confirmation**

Ultrasonography for aortic–iliac thrombosis.
ETIOLOGY
Injury to vascular endothelium, alteration to normal blood flow (turbulence or stasis) and alterations to the coagulability of blood can predispose thrombosis and thromboembolism.

Coagulopathies
Coagulopathies and disseminated intravascular coagulation are important in the pathogenesis thromboembolism, which occurs in many infectious diseases.1

Parasitic arteritis
- Strongylus vulgaris - horses. Migrating larvae cause arteritis of the anterior mesenteric artery, iliac arteries, base of aorta and occasionally cerebral, renal or coronary arteries. This is a major cause of arteritis and associated clinical disease in horses6
- Aortic–iliac thrombosis in horses. There is some controversy over the etiology of this disease. It may result from strongyle-related thromboembolism with organization of thrombi and their incorporation into the arterial wall with centripetal development of progressive thrombosis. Alternatively spontaneous degenerative vascular disease of unknown etiology, but particularly at the aortic quadrifurcation may result in thrombosis in the area and subsequently thromboembolism of more distal vessels
- Onchocerciasis and elaeophorisis in cattle, sheep, goats, and horses.

Viral arteritis
- Important in pathogenesis of several viral diseases, including malignant catarrhal fever, equine viral arteritis, African swine fever, hog cholera, bluetongue, African horse sickness.

Bacterial arteritis
- Including septicemic salmonellosis, erysipelas, Histophilus somni, Haemophilus pleuropneumoniae, pasteurellosis.

Embolic arteritis and thromboembolism
- From vegetative endocarditis or emboli from arterial thrombus in various sites
- Hyperlipemia and hyperlipidemia in horses
- Fat emboli following surgery
- Associated with subclinical Salmonella dublin infection in calves
- Rupture of abscesses into blood vessels – pulmonary embolism resulting from caudal vena caval thrombosis or jugular thrombosis
- From indwelling catheters.

Microangiopathy
- Vitamin E/selenium deficiency
- Cerebrospinal angiopathy
- Terminal in most septicemic disease.1

Calcification
- Enzootic calcinoses
- Vitamin D toxicity
- Chronic hypomagnesemia in calves
- Lymphosarcoma in some horses.

Vasoconstrictive agents
- Ergot poisoning
- Fescue poisoning.

EPIDEMIOLOGY
Clinical atherosclerosis occurs rarely in farm animals. It has been recorded in a horse in which sufficient vascular obstruction occurred to cause severe central nervous signs and a fatal outcome. Spontaneous atherosclerosis is a common necropsy finding in swine, cattle, goats, horses and wild animals but is not associated with clinical disease. Arteriosclerosis and calcification are major findings in enzootic calcinoses and occur following overdosing with vitamin D or its analogs in the prevention of milk fever in cattle and in hypomagnesemia in calves.

PATHOGENESIS
In parasitic arteritis, inflammation and thickening of the arterial wall result in the formation of thrombi, which may partially or completely occlude the artery. The common site is in the anterior mesenteric artery, obstruction of the vessel causing recurrent colic or fatal ischemic necrosis of a segment of the intestine. Less common sites include the origin of the iliac artery at the abdominal aorta causing iliac thrombosis, the base of the aorta leading to rupture and hemopericardium, and the coronary arteries causing myocardial infarction.

With other causes of arteritis, the clinical syndrome is dependent upon the site of arteritis or embolism. Arteritis associated with bacterial and viral infec­tions is usually widespread and several organ systems are involved. Bacterial emboli have a predilection to lodge in:
- Vascular plexuses in the kidney to produce renal disease
- The synovial membranes to produce arthritis and tenosynovitis
- The endocardium to produce endocarditis.

Less commonly, they may lodge in other vascular plexuses such as the rete cerebi. Large emboli that lodge in the pulmonary arteries cause anoxic anoxia. Embolism in the renal artery causes acute cortical necrosis and gross hematuria.

Vasoconstrictive alkaloids produced by Claviceps purpurea infestation of grass seed heads and Acremonium coenophialum, which infects Festuca arundinacea and Lolium perenne, cause arteriolar constriction and result in ischemic necrosis and gangrene of distal extremities in cattle.

CLINICAL FINDINGS
The clinical findings in mesenteric verminous arteritis of horses and renal, and myocardial infarction, gangrene associated with C. purpurea or endophyte infestation of grasses and other diseases listed above are described elsewhere under those headings. The clinical signs of aortic–iliac thrombosis and pulmonary embolism are described here.

Aortic–iliac thrombosis in the horse
Aortic–iliac thrombosis34 is reported most commonly in racehorses but occurs in other breeds. It is primarily a disease of horses of over 3 years of age. Either one or both hindlegs may be involved. The clinical manifestations vary according to the stage of progression of the disease and are associated with ischemia of the hindlimbs.

Early mild cases are usually detected in racehorses or horses subjected to maximal exertion where the disease may be a cause of poor performance. In early cases there is lameness only on exercise, the animal returning to normal after a short rest. If the horse is forced to work when lameness develops, the signs may increase to resemble those of the acute form. The lameness takes the form of weakness, usually of one hindlimb, which tends to give way, especially when the animal turns on it. Frequent lifting of the foot or cow-kicking may also be shown.

In more severe cases, lameness or refusal to work may be evident after minimal exercise:

The disease is chronic and progressive, but occasionally the onset may be acute.

In the acute form there is great pain and anxiety and the pulse and respiration rates are markedly increased. Profuse sweating may be evident, but the affected limb is usually dry and may be cooler than the rest of the body. The pain is often sufficiently severe to cause the animal to go down and refuse to get up.

Suspect animals should be examined following exercise:
- The affected limb is cool from the mid-gaskin distally and there is usually diminished or variable sweating over this area
- The amplitude of the pulse in the common digital artery is less in the affected limb than in the normal limb or the front limbs
- Slow filling of the saphenous vein of the affected limb can usually be detected
- Palpable abnormalities on rectal examination include enlargement
and firmness of the aortic quadrifurcation, irregularity and asymmetry of the internal and external iliac arteries and decreased amplitude or absence of an arterial pulse.

Recovery by the development of collateral circulation or shrinkage of the thrombus is unlikely to occur and the disease is usually chronically progressive with a poor prognosis.

Until recently the detection and diagnosis of the occurrence of this abnormality was limited to horses showing clinical signs and horses where abnormality could be palpated on rectal examination. Ultrasonography is a more sensitive method of detection than rectal palpation. Its use as a diagnostic technique may lead to a better definition of the occurrence of this disease and ultimately its pathogenesis. Ultrasonographic measurements are available for the common carotid artery of cattle.6

Iliac thrombosis may also be associated with impotence in stallions due to failure to mount or accompanied by testicular atrophy.7 It has also been associated with a syndrome of ejaculatory failure in which the stallion has excellent libido, good coupling and vigorous thrusting but a failure to ejaculate.8 The reason for this manifestation is not known but it is postulated that the enlarged arteries might impinge on the caudal mesenteric plexus and the hypogastric nerve.8

Aortic-iliac thrombosis in calves
Aortic and iliac artery thrombosis is reported as an occasional disease of unknown etiology in calves less than 6 months of age.9 Affected calves have a sudden onset of ataxia, paresis or paralysis of one or both hind limbs. Within 24 hours of onset the calves do not bear weight on the affected leg and, in calves affected in both hindlimbs, signs initially occur in a single limb. Affected legs are cold to touch, especially distal to the stifle, have poor muscle tone and the withdrawal reflex and deep pain sensation is absent in the distal portions. Subcutaneous swelling and crepitation is present in some. Thrombosis at the terminal part of the aorta and the iliac quadrifurcation is found at postmortem examination. The umbilical arteries arise from the iliac arteries near the iliac quadrifurcation and it is thought that thrombus formation in the iliac arteries may predispose to this disease.

Pulmonary embolism
Severe dyspnea develops suddenly and is accompanied by profuse sweating and anxiety. The temperature and pulse rate are elevated but the lungs are normal on auscultation. In horses the signs usually pass off gradually in 12–24 hours but in cattle the hypoxemia may be more severe and cause persistent blindness and imbecility. Infected emboli may lead to more severe pulmonary embolic disease with arteritis and pulmonary abscessation. There is pulmonary hypertension, and cor pulmonale is a possible sequel. Pulmonary arteritis and aneurysm may be followed by rupture and pulmonary hemorrhage and hemoptysis.

CLINICAL PATHOLOGY
Extensive thrombus formation is usually associated with a leukocytosis and a shift to the left and there is an increase in serum fibrinogen concentration. In the majority of cases of iliac thrombosis serum aspartate aminotransferase and creatine kinase activities are within the normal range both before and after exercise but in severe cases there may be enzymic evidence of myonecrosis with secondary hyperkalemia and uremia.10 Elevated serum creatine kinase and aspartate transaminase activities are present in aortic and iliac thrombosis in calves. Angiography or ultrasonography are used for diagnostic confirmation.

NECROPSY FINDINGS
Obstruction of the affected artery is easily seen when it is opened. The thrombus or embolus is adherent to the intima and is usually laminated. Local or diffuse ischemia or infarction may be evident if the embolus has been present for some time and may have progressed to the point of abscess formation.

DIFFERENTIAL DIAGNOSIS

Aortic-iliac thrombosis in the horse
- Paralytic myoglobinuria
- Hyperkalemic periodic paralysis
Aortic-iliac thrombosis in calves
- Vertebral osteomyelitis (spinal abscess)
- White muscle disease
- Vertebral fracture
- Clostridial myositis
- Pulmonary embolism
- Pneumonia.

TREATMENT
Treatment with parenteral anticoagulants or enzymes is carried out only rarely. There are several records of good results in iliac thrombosis in horses after the intravenous injection of sodium glucuronate or fibrinolytic enzymes,10 and retrograde catheterization of the ventral coccygeal artery can allow the deposition of these materials at high local concentration. Stallions with ejaculatory failure have had some success at service following treatment with phenylbutazone to reduce pain and and gonadotropin-releasing hormone to maximize sexual arousal and lower the ejaculatory threshold.8 Ivermectin in combination with phenylbutazone may aid recovery. A gradually increasing exercise program may improve collateral circulation. Surgical treatment is recorded by partial or complete removal of the thrombus with a thrombectomy catheter.8

REFERENCES

VENOUS THROMBOSIS
The development of thrombi in veins may result in local obstruction to venous drainage, in liberation of emboli that lodge in the lungs, liver or other organs, and in the development of septicemia or of endocarditis.

PHLEBITIS
Phlebitis is the common origin of thrombi and may be caused by localization of a blood-borne infection, by extension of infection from surrounding diseased tissues, by infection of the umbilical veins in the newborn and by irriant injections into the major veins.

Thrombophlebitis of the jugular vein is a complication of injections or catheterization in some animals and occurs in all species. It can result from damage to the vascular endothelium by cannula or indwelling intravenous catheters, inflammation caused by chemical irritation or bacterial invasion from contamination during insertion of the needle or catheter or migration along the catheter from the skin.1,2 Phlebitis develops and can be detected clinically 24–72 hours after catheter insertion. A retrospective study of 46 cases in horses indicated that ongoing infectious disease was a risk factor for the development of catheter-associated thrombophlebitis3 and thrombophlebitis is especially common in horses with severe gastrointestinal diseases that are accompanied by endotoxia. Horses are also at higher risk following surgery.2 Severely ill cows are more likely to develop jugular vein thrombophlebitis than healthy cows.2
Intravenous injections of irritating materials, such as tetracycline, phenylbutazone, 50% dextrose, hypertonic solutions of calcium gluconate, borogluconate and chloride, or hypertonic saline (7.2% NaCl), may cause endothelial damage followed by cicatricial contraction, with or without thrombus formation. Jugular phlebitis with thrombosis is not uncommon in feedlot cattle that have received repeated intravenous antibiotic medication, and may lead to thromboembolic respiratory disease.

Accidental injection of irritating materials around the vein usually cause a marked local swelling, sometimes with necrosis and local sloughing of tissue, which may be followed by cicatrical contraction of local tissues.

Phenylbutazone

Commonly used as an NSAID, its use in horses may be associated with toxicity, which is manifest with oral and gastrointestinal ulceration and renal medullary crest necrosis.\(^6\)\(^-\)\(^7\) Affected horses show depression, anorexia and neutropenia with ulcers in the mouth, especially on the ventral aspect of the tongue. Ulcers in the fundic and pyloric portion of the stomach also develop but are usually subclinical, although they may be evident on gastroscopic examination or at necropsy. More severe cases show signs of colic and diarrhea in association with intestinal ulceration and duodenitis, and show evidence of renal disease. Toxicity may develop following either intravenous or oral administration of the drug. Intravenous administration is frequently associated with the development of phlebitis and jugular thrombosis at the site of injection.

Phlebitis may also develop in these animals at sites of venepuncture performed for purposes other than phenylbutazone administration. Experimental studies\(^8\)\(^-\)\(^10\) suggest that a phlebopathy induced by phenylbutazone is central to the development of all these lesions, including the oral and gastrointestinal ulceration and the renal crest necrosis. The exact pathogenesis of the vein damage in phenylbutazone toxicity has not been elucidated but, experimentally, toxicity can be prevented by the concurrent administration of prostaglandin \(E_2\).\(^7\) Clinical pathological examination for leukopenia and a fall in serum aspartate aminotransferase may be of value as a monitoring technique for the development of toxicity during phenylbutazone therapy of disease.

Venous thrombi are relatively common in strangles in the horse, and may affect the jugular veins or the caudal vena cava. Thrombosis of the caudal vena cava due to hepatic abscessation and resulting in embolic pneumonia and pulmonary arterial lesions occurs in cows and is described together with cranial vena caval thrombosis in Chapter 10.

Less common examples of venous thrombosis are those occurring in the cerebral sinuses, either by drainage of an infection from the face or those caused by the migration of parasite larvae. Purpling and later sloughing of the ears which occur in many septicaemias in pigs are also caused by phlebitis and venous thrombosis. Thrombosis of the tarsal vein is a complication of infections in the claw of cattle\(^7\) and intravenous administration of antimicrobial agents as part of the treatment of septic arthritis or the distal interphalangeal joints.

CLINICAL SIGNS

Clinical signs of venous thrombosis are engorgement of the vein, pain on palpation and local edema. In unsupported tissues rupture may occur and lead to fatal internal or external hemorrhage. Ultrasonographic examination assists the diagnosis and the detection of a cavitating area within the thrombus supports a diagnosis of septic thromboembolitis.\(^3\)\(^,\)\(^5\)\(^,\)\(^8\) Angiography can also assist in diagnosis. Bacteriological culture should be attempted, preferably from the tip of the removed catheter. A variety of different organisms have been isolated from different cases.\(^3\) There are no typical findings on clinicopathological examination but there is often an abnormal leukogram and hyperfibrinogenemia. At necropsy the obstructed vessel and thrombus are usually easily located by the situation of the edema and local hemorrhage.

Diagnosis depends on the presence of signs of asymmetric local venous obstruction in the absence of obvious external pressure by tumor, enlarged lymph nodes, hematomas or fibrous tissue constriction. Pressure of a fetus may cause symmetric edema of the perineum, udder and ventral abdominal wall during late pregnancy, and can be easily differentiated from thromboembolitis by its symmetry and lack of pain. Local edema due to infective processes such as blackleg, malignant edema and peracute staphylococcal mastitis are accompanied by fever, severe toxemia, acute local inflammation and necrosis.

TREATMENT

Parenteral treatment with antimicrobial agents and hot fomentations to external veins, or treatment with a topical anti-inflammatory agent such as 50% dimethyl sulfoxide, is usually instituted to remove the obstruction or allay the swelling. If a catheter is being used it should be immediately removed. Heparin and warfarin treatment in horses is not recommended.\(^9\) Ultrasonography is useful to monitor recanalization of the thrombosed vein and measurements of the external jugular vein are available for cattle.\(^10\)

HEMANGIOMA AND HEMANGIOSARCOMA

Hemangiomia and hemangiosarcoma are rare in large animals but are described and may be associated with hemorrhage related to the site of the tumor.

HEMANGIOMA

Hemangiomas in the skin occur most commonly in young animals and may be congenital.\(^1\)\(^,\)\(^2\) The tumors grow with age; those on the skin may ulcerate and bleed and may necessitate euthanasia because of their eventual size. Similar tumors may occur in the mouth as pedunculated pink granular masses that ulcerate and bleed. Local hemangiomia on the skin and in the mouth may respond to surgical excision, thermocautery or radiation therapy. Widespread disseminated hemangiomia is also recorded in young cattle presenting with multiple skin lesions and multigorgan involvement.\(^3\)\(^,\)\(^4\) Hemangiomia has also been reported with moderate prevalence affecting the ovaries of sows.\(^5\)

HEMANGIOSARCOMA

Hemangiosarcoma occurs in horses but is not a common tumor. It is more prevalent in middle-aged and older animals. Affected horses may present with a bleeding subcutaneous mass or with signs of disseminated hemangiosarcoma. Disseminated hemangiosarcomas in horses cause anemia due to hemorrhage into the tumor or into body cavities. In addition there is weight loss, but good appetite, and weakness. Metastasis is extensive to lung, myocardium, brain, retroperitoneum and skeletal muscle.\(^5\)\(^-\)\(^8\) and myocardial lesions can lead to cardiac arrhythmias. Lesions in skeletal muscle cause difficulties in movement and tumors in the nervous system...
present with signs of ataxia. The thoracic cavity is a common site for metastasis and can also be a primary site of the neoplasm.

A common clinical manifestation is pleural effusion and hemorrhage and a clinical picture which requires differentiation from other causes of thoracic mass with effusion, which in the horse is more commonly mediastinal abscess, lymphosarcoma, squamous cell carcinoma or pleurisy. Hemoperitoneum, detectable by paracentesis, is present with peritoneal tumors. All the tumors are cavitatious and bleed profusely if incised. Early histopathologic diagnosis may permit a cure in animals with localized masses that can be surgically resected. If masses are not interfering with quality of life and the horse is medically stable, observation may be warranted because spontaneous resolution has been reported.

**RHABDOMYOSARCOMA**

Primary cardiac rhabdomyosarcoma occurs rarely in cattle and sheep.

Abnormalities of plasma protein concentration

Plasma contains hundreds of proteins, including albumin, immunoglobulins, clotting factors, acute phase proteins, hormones and cytokines. The proteins in plasma are produced by the liver (albumin, acute phase proteins (fibrinogen, serum amyloid A), clotting factors) and lymphoid organs (the gamma-globulins and many cytokines). The plasma proteins serve as sources of amino acids for tissues, as carrier molecules, maintain plasma oncotic pressure, regulate immune function, and effect hemostasis and fibrinolysis. Defects or deficits of individual proteins can result in specific diseases, including immune deficiency, defective hemostasis and endocrinopathy. The individual diseases resulting from loss of activity of specific proteins are dealt with under the headings of those diseases. Provided here is an overview of hypoproteinemic and hyperproteinemic states.

HYPOPROTEINEMIA

ETIOLOGY

Hypoproteinemia is a plasma or serum total protein concentration that is below that expected in animals of the same age, sex, physiological state and species. Hypoproteinemia can be a result of a reduction in concentration of albumin and globulin, or a reduction in either albumin or globulin concentrations. Abnormalities in plasma protein concentration include:

- Hypoproteinemia with hypoalbuminemia and normal globulin concentration
- Hypoproteinemia with hypoglobulinemia and normal albumin
- Normal total protein concentration with hypoalbuminemia and hyperglobulinemia, and less commonly, hyperalbuminemia and hypoglobulinemia.

The specific deficiency has important diagnostic significance.

Panhyproteinemia

Hypoproteinemia with hypoalbuminemia and hypoglobulinemia can be either relative or absolute. Relative hypoproteinemia occurs when plasma protein concentrations are lower than normal but the absolute content of protein in the vascular space is normal. This is a dilutional hypoproteinemia and is attributable to either excessive fluid therapy or excessive water intake. These causes are readily determined from a review of the history and treatment of the animal and resolve within hours of discontinuation of fluid therapy or restriction of fluid intake.

Absolute hypoproteinemia occurs when there is a reduction in the amount of plasma proteins in the vascular space in the presence of normal or almost normal plasma volume. The reduced protein concentration can be the result of impaired production or accelerated loss. Reduced production of all plasma proteins occurs only as part of malnutrition and starvation. Liver disease can cause a reduction in the concentration in plasma of those proteins produced by the liver (see below) but in large animals is an unusual cause of hypoproteinemia. Loss of protein is a more common cause of hypoproteinemia.

The loss of proteins can be either from the vascular space into the extravascular compartment (e.g. endotoxemia, vasculitis) or from the body (compensated hemorrhage, glomerulonephritis, protein-losing enteropathy). This situation is evident as a reduction in concentrations of both albumin and globulins, and in hemorrhagic disease by a reduction in hematocrit. Loss because of vascular leakage is usually evident as hypoproteinemia with normal or elevated hematocrit. Diseases causing panhyproteinemia include:

- Hemorrhage – hypoproteinemia occurs when plasma volume is restored after severe hemorrhage, or in normovolemic anemia when there is persisting loss of blood (see page 451 for a list of diseases causing chronic hemorrhagic anemia). All causes of chronic blood loss can cause hypoproteinemia
- Endotoxemia – protein loss is secondary to leakage of protein from the vascular space into interstitial spaces because of increased capillary permeability
- Vasculitis – causing increased capillary permeability and leakage of protein. Evident in many systemic diseases, including African horse sickness, purpura hemorrhagica, swine fever, and malignant catarrhal fever
- Protein-losing enteropathy – the initial change is in plasma albumin concentration, but panhyproteinemia ensues as the disease progresses. Diseases causing protein-losing enteropathy include:
  - Intestinal parasitism
  - Abomasal ulceration in cattle
Lymphosarcoma in cattle and horses
- Granulomatous/inflammatory
  intestinal disease in horses
  (granulomatous enteritis,
  eosinophilic enteritis) and cattle
  ( Johne’s disease)
- Enteritis/celitis (salmonellosis,
  equine neorickettiosis
  (Neorickettsia risticii))
- Nonsteroidal anti-inflammatory
  drug (NSAID) toxicosis
- Lawsonia intracellularis proliferative
  enteropathy in young horses and
  pigs
- Urinary tract disease including cystic
  calculi, pylonephritis,
  glomerulonephritis
- Acute, severe inflammation of the
  peritoneal or pleural membranes
  (peritonitis, pleuritis). The
  hypoproteinemia occurs early in
  the disease but if the disease becomes
  chronic hypergamaglobulinemia
  ensues
- Chronic heart failure.

Hypalbuminemia
Hypalbuminemia with normal or elevated
plasma globulin concentration occurs in
diseases in which there is insufficient
production of albumin by the liver or
excessive or selective loss of albumin
compared to loss of globulin. Insufficient
production of albumin occurs in diseases
of the liver, although these animals might
not necessarily be hypoproteinemic and
malnutrition or starvation. Diseases of the
liver that cause hypalbuminemia are
usually diffuse, severe and chronic. The
prolonged half-life of albumin in cattle
and horses (approximately 18 d) renders
them less liable to hypalbuminemia than
smaller animals.

Albumin has a lower molecular weight
than most globulins, especially the
immunoglobulins, and can be lost selec-
tively in renal or gastrointestinal disease.
Diseases associated with hypalbumi-
minemia and normal to elevated globulin
concentrations include:
- Amyloidosis – loss of albumin into
  urine or the gastrointestinal tract is
  sometimes offset, in terms of plasma
  protein concentration, by increases in
  plasma globulin concentration
- Chronic peritonitis or pleuritis – loss of
  albumin into the inflammatory exudate
  is offset, in terms of plasma total
  protein concentration, by increases in
  plasma globulin concentration
- Intestinal parasitism
- Renal disease
- Glomerulonephritis – because of
  changes in the size and charge on
  proteins of the glomerular
  membrane, albumin is not
  prevented from entering the
  ultrafiltrate and is lost in urine. Any
diseases affecting the glomeruli
  can cause albumin loss
- Pyelonephritis

Hypogammaglobulinemia
Hypogammaglobulinemia with normal plasma
albumin concentration occurs in few
diseases. Notably, it is a feature of failure
of transfer of passive immunity in neonates
(Ch. 3). Hypogammaglobulinemia is an unusual
isolated defect in other diseases. It can be
detectable in immunodeficiencies causing
decreased production of gammaglobulins,
such as combined variable immunodefi-
cency in horses.2

Hypofibrinogenemia
This only occurs as part of disseminated
intravascular coagulation.

PATHOPHYSIOLOGY
Panhypoproteinemia and hypoalbumi-
inemia cause a reduction in concentra-
tion in plasma of proteins essential for a
variety of functions. Overall, the reduction
in plasma albumin concentration results
in a low plasma oncotic pressure. Low
plasma oncotic pressure allows move-
ment of fluid from the vascular space,
causing a reduction in plasma volume
and increases in extravascular volume.
The reduction in plasma volume lowers
blood flow to tissues and can result in
organ dysfunction. The increased extra-
vascular volume is evident as edema.

Low plasma albumin concentration, in
addition to the reduction in plasma oncotic
pressure, reduces opportunities for trans-
port of substances in the plasma, includ-
ing hormones and electrolytes (calcium).

Hypogammaglobulinemia increases
the risk of infectious disease (see Ch. 3).

CLINICAL SIGNS
The clinical signs of hypoproteinemia are
lethargy, ill-thrift and edema. The edema
is usually distributed symmetrically,
with some species predilection for site of
accumulation – ventral edema in horses,
submandibular edema in cattle and sheep.
Affected animals are often tachycardic
because of the reduced plasma volume.

Signs of the inciting disease will also be
present (weight loss, diarrhea, melena,
polyuria).

CLINICAL PATHOLOGY
Detection of hypoproteinemia is readily
achieved by routine hematologic or serum
biochemical testing. The albumin to
globulin (A:G) ratio can be useful in
assessment of the hypoproteinemia.
Hypoproteinemia with normal globulin
concentration results in a low A:G ratio,
whereas panhypoproteinemia results in a
normal A:G ratio. Selective deficiencies
can be detected by protein electro-
phoresis or measurement of concen-
trations of specific proteins, such as the
immunoglobulins by enzyme-linked
immunosorbent assay (ELISA), radial
immunodiffusion (RID), or immunotur-
bidimetric analysis (see Failure of transfer
of passive immunity in Ch. 3).

Measurement of plasma oncotic pressure is useful in
detecting low plasma oncotic pressure, which contributes to
a reduction in plasma volume and increases in extravascular fluid which can lead to
formation of edema. Plasma oncotic pressure is proportional to the plasma protein concentration, with the greatest
correlation being with plasma albumin concentration in animals that have not
received dextran solutions. Intravenous administration of dextran or hydroxyethyl
starch increases plasma oncotic pressure.

NECROPSY
The changes are those of the inciting
disease, or secondary infection in animals
with hypogammaglobulinemia. Edema
can be present in subcutaneous and
internal connective tissues.

TREATMENT
The principles of therapy are treatment of the inciting disease, and correction of
hypoproteinemia or low plasma oncotic
pressure. Correction of hypoproteinemia
(hypalbuminemia, hypogammaglobul-
inemia) is achieved by administration of
plasma by transfusion. Unless anemia is
also present, plasma transfusion is preferred
over blood transfusion. The amount of
plasma transfused to neonates is dis-
cussed in Chapter 3. Plasma transfusion
to adult horses and cattle is often limited
by the cost of the plasma. Ideally, plasma
should be transfused to increase plasma
albumin concentrations to more than
2.0 g/dL (20 g/L). This can be calculated as
(where 0.05 is the proportion of body
weight that is plasma):

\[
\text{Current plasma albumin content} = \text{body weight (kg)} \times 0.05 \times (\text{plasma albumin concentration in g/L})
\]

\[
\text{Desired plasma albumin content} = \text{body weight (kg)} \times 0.05 \times (\text{desired albumin concentration in g/L})
\]

\[
\text{Amount of albumin required (g)} = \text{Desired plasma albumin content} - \text{current albumin content}
\]

\[
\text{Volume of plasma required (L)} = \text{Amount of albumin required (g)/albuniin concentration in transfused plasma (g/L)}.
\]

A numerical example is of a 500 kg horse
with a plasma albumin concentration of
1.5 g/dL (15 g/L) and a target plasma
albumin concentration of 2.5 g/dL (25 g/L):

\[
\text{Current plasma albumin content} = 500 \text{ (kg)} \times 0.05 \times 15 \text{ (g/L)} = 375 \text{ g}
\]
**Desired plasma albumin content =**

\[500 \text{ (kg)} \times 0.05 \times 25 \text{ (g/L)} = 525 \text{ g}

**Amount of albumin required (g)**

\[525 - 375 = 150 \text{ g}

**Volume of plasma required (L)**

\[150 \text{ (g)} / 30 \text{ (g/L)} = 5 \text{ L}

It is a frequent observation that transfusion of the calculated volume of plasma, while improving clinical signs, does not result in the expected increase in plasma albumin concentration. This is probably because transfusion of albumin results in an increase in plasma oncotic pressure and a net movement of fluid from the extravascular space into the vascular space with subsequent expansion of the plasma volume. The expansion of plasma volume dilutes the administered albumin and attenuates the increase in plasma protein concentration.

Plasma oncotic pressure can be increased by intravenous administration of hydroxyethyl starch or high-molecular-weight dextrans. The dose is 8–10 mL/kg of 6% solution delivered intravenously over 6–12 hours.1,2

**HYPERPROTEINEMIA**

**ETIOLOGY**

Panhyperproteinemia

An increase in concentration of all plasma proteins occurs only in situations in which there is a reduction in plasma water content. This occurs in animals that are severely dehydrated through lack of access to water, inability to drink, loss of protein-poor body fluids (diarrhea, vomitus) or excessive polyuria with inadequate water intake.

Hyperglobulinemia

Hyperglobulinemia occurs as a consequence of chronic inflammation or abnormal production of globulins. Chronic inflammation causes a polyclonal gam­mopathy whereas plasma cell neoplasia (plasmacytoma, myeloid leukemia, see ‘Leukoproliferative disease’) causes a monoclonal gammopathy. Any chronic inflammatory disease, including those of infectious, toxic or neoplastic origin, can cause hyperglobulinemia.

Hyperfibrinogenemia

Fibrinogen is an acute phase protein (along with serum amyloid A, haptoglobulin, C-reactive protein and others) the concentration of which increases in plasma in response to inflammation. Any disease that causes inflammation can increase plasma fibrinogen concentration.

**PATHOPHYSIOLOGY**

Chronic inflammation results in chronic stimulation of the immune system with subsequent increased production of immune globulins and acute-phase proteins. Monoclonal gammaglobulinemia occurs as a result of unrestrained production of gammaglobulins by neoplastic plasma cells.

**CLINICAL SIGNS**

The clinical signs are of the underlying inflammatory disease.

**CLINICAL PATHOLOGY**

Measurement of plasma protein concentration reveals hyperglobulinemia and/or hyperfibrinogenemia. Serum protein electrophoresis demonstrates whether the abnormality is a polyclonal or monoclonal gammaglobulinopathy. Measurement of specific immunoglobulins (IgG, IgA, etc.) can be useful. Fibrinogen concentration must be measured in plasma as it is consumed during the clotting process when blood is allowed to clot.

**NECROPSY**

The findings are those of the underlying disease.

**TREATMENT**

Treatment is directed towards the underlying disease.

**REFERENCES**

---

**Hemorrhagic disease**

Hemorrhagic disease is manifest as the presence of hemorrhage of unusual duration or severity, either externally from apparently minor wounds, or into body cavities, or as the presence of petechial and ecchymotic hemorrhages in mucous and conjunctival membranes and the skin. Petechial and ecchymotic hemorrhage, spontaneous hemorrhage or excessive bleeding after minor injury may result from increased capillary fragility, disorders in platelet function or defects in the coagulation mechanism of the blood.

**Diagnosis**

Diagnosis of hemorrhagic disease is based on the demonstration of abnormalities in the activity, concentration or function of components of blood coagulation and fibrinolysis. The exception is diagnosis of vasculitis, which is achieved by biopsy, usually of skin, and histologic examination and demonstration of inflammatory lesions in the walls of blood vessels.

Demonstration of prolonged bleeding time is achieved using devices that inflict a controlled wound on either the skin or a mucous membrane (template bleeding time). A wound is inflicted in the skin and blood is periodically collected on to absorbent filter paper until bleeding ceases. The time from discharge of the device until bleeding stops is the ‘bleeding time’. The mean template bleeding time is less than 5 minutes in most healthy animals.1

Care must be taken when collecting specimens of blood for measurement of factors involved in coagulation or fibrinolysis. Blood samples collected into containers that do not contain an anticoagulant will rapidly clot and the resulting serum sample will be minimally useful for any tests of clotting or fibrinolysis. The ideal anticoagulant for assays of clotting and fibrinolysis is trisodium citrate (1 part of 3.8% trisodium citrate to 9 parts of blood). Sodium citrate decreases the concentration of ionized calcium in blood and thereby inhibits platelet activity.3 Heparin, both unfractionated (conventional) and low-molecular-weight inhibits thrombin activity and activates platelets and is not a suitable anticoagulant for measurement of clotting times or platelet activity.2 Potassium ethylenediamine tetraacetic acid (EDTA) interferes with platelet function.

An integrated measure of the capacity of blood to clot is the activated clotting time. In this test, blood is collected into plastic syringes that do not contain an anticoagulant and then immediately injected into glass tubes containing diatomaceous earth. The tubes are gently agitated and then incubated for 1 minute in a water bath at 37°C. The tubes are then removed from the water bath and examined for clotting of blood by gently rolling the tube. The tube is then returned to the water bath and reexamined every 30–60 minutes.

The rate of clot retraction of blood collected into a glass tube that does not contain anticoagulants is a measure of platelet activity. The time until maximum clot retraction is 1–2 hours in most species when the blood is held at 37°C. Measurement of prothrombin time (an indicator of activity of the extrinsic clotting system), activated partial thromboplastin time (an indicator of functionality of the intrinsic clotting system) and thrombin time (common pathway) are routinely performed for animals. The tests are reliable when performed properly; however, values for normal animals can vary and the recommendation is that, when submitting a sample from an animal with suspected coagulopathy, a sample from a similar healthy animal should also be examined. If prothrombin or activated partial thromboplastin time are prolonged, other tests to determine the specific factor(s) involved might be warranted.

Measurement of the activity or concentration of blood clotting factors is
von Willebrand factor is available that is including horses, pigs, and cattle. While much more useful than PDP in assessment of fibrin (fibrinogen) degradation products (FDP) has been used to detect disseminated intravascular coagulation in horses but the test has poor sensitivity and specificity. Measurement of d-dimer concentration has the potential to be much more useful than FDP in assessment of fibrinolysis and detection of thromboembolic disease, including disseminated intravascular coagulation and coagulopathies. Performance characteristics vary among assays and kit suppliers. The FDP assays had low sensitivity (< 40%), whereas the most accurate d-dimer kit had 50% sensitivity and 97% specificity for diagnosis of disseminated intravascular coagulation in horses with colic.

The activity of antithrombin (previously antithrombin III), a cofactor of heparin, is measured in plasma kept at various temperatures. Impaired platelet aggregation can be detected as a prolongation in closure time using cartridges with collagen–adenosine diphosphate (CT-ADP) and collagen–epinephrine (CT-Epi) as platelet agonists. In normal horses calculated reference ranges are 60.5–115.9 seconds and 158.5–300 seconds for CT-ADP and CT-Epi, respectively.

Values of the above variables in normal animals have been reported inconsistently and are available in textbooks dealing with hematology. Values in foals and calves of increasing age are reported.

### Treatment of coagulopathies

#### Plasma

Plasma is often administered to animals with hemorrhagic diatheses to replace clotting factors that are deficient because of failure of production (e.g. warfarin intoxication), increased consumption (e.g. in disseminated intravascular coagulation) or dilution (e.g. in animals with severe hemorrhage treated by administration of large quantities of fluids). The actual concentration or activity of factors involved in clotting or fibrinolysis depends upon the methods used to collect and store the plasma. Fresh frozen plasma kept at −80°C retains much of the activity of clotting factors (VII, VIII, etc.) and inhibitors of coagulation, including antithrombin, protein C, protein S and antitrypsin, for up to 1 year, whereas plasma stored at higher temperatures might not retain as much activity. The dosage varies from 2–10 mL/kg body weight (BW) intravenously, but this has not been critically evaluated. Platelet-rich plasma, which requires more sophisticated collection techniques, is useful for treatment of severe thrombocytopenic purpura. Platelet-rich plasma can be prepared by centrifugation of blood at 150 x g for 20–30 minutes. Plasma is preferred over whole blood for treatment of nonanemic hemorrhagic diatheses.

#### Aminocaproic acid

(30–100 mg/kg intravenously) reduces plasma fibrinogen concentration and decreases partial thromboplastin time of horses for up to 5 hours after administration. At the higher dose, alpha-2-antiplasmin activity is increased and fibrinogen concentration is decreased, consistent with an action of the drug to inhibit fibrinolysis. The utility of aminocaproic acid to inhibit bleeding in clinical situations has not been determined.

#### Tranexamic acid

Inhibits fibrin degradation and is used as adjunctive treatment in animals with hemorrhagic diathesis. Its efficacy in farm animals has not been reported. Carbazochrome is a compound that stabilizes capillary membranes and is used for treatment of exercise-induced pulmonary hemorrhage in horses, although with undetermined efficacy.

#### Formalin

Has been suggested as an effective treatment of excessive hemorrhage in horses, although it does not appreciably alter bleeding time or indices of coagulation. A common dose for an adult horse is 1 L isotonic electrolyte solution (saline or lactated Ringer’s solution) with a final concentration of formalin of 0.37–0.74%. Adult goats administered a 5.5% solution of formalin in lactated Ringer’s solution intravenously had a marked decrease in clotting time. However, this dose in horses is expected to be toxic.

Administration of aspirin to horses inhibits platelet function in a dose-dependent fashion for 48 hours after a single dose of 12 mg/kg. This is not the case in cattle, in which aspirin does not inhibit platelet aggregation even at doses of 100 mg/kg orally. Aspirin irreversibly inhibits activity of thromboxane synthetase in both cattle and horses for a prolonged period (days) despite having a short plasma elimination half-life (hours). The bleeding time in horses is not restored until the affected platelets have been replaced by unaffected platelets.

Doses of aspirin in horses range from 15–100 mg/kg orally every 8–12 hours to 10 mg/kg orally every 48 hours.

#### Warfarin

Reduces the concentration of vitamin-K-dependent clotting factors by inhibiting hepatic production of these compounds. Therapeutic use of warfarin was limited to treatment of navicular disease in horses, although its use for this purpose is now archaic.

#### Heparin

And the newer heparin-related compounds (low-molecular-weight heparins) dalteparin and enoxaparin, have been used in horses with, or at risk of developing, coagulopathies. The low-molecular-weight heparins appear to be effective in reducing the frequency of coagulopathy in horses with colic without the adverse effect of heparin on
hematocrit and clotting time.\textsuperscript{22} Calcium heparin causes in-vivo red cell aggregation in horses, with a resultant reduction in hematocrit and hemoglobin concentration and a reduction in platelet count.\textsuperscript{7,11-23} The low-molecular-weight heparins are dosed on the basis of anti-factor-Xa activity. At doses of these compounds that prolong factor Xa activity and thrombin time, they have a minimal effect on bleeding time or activated partial thromboplastin time in horses.\textsuperscript{20,22,24} A range of once daily to horses.\textsuperscript{24} 

The clinical efficacy of recombinant hirudin has not been determined.\textsuperscript{27,28} Hemorrhagic tendencies in the walls.\textsuperscript{27,28} Hemorrhagic diathesis in animals that is discussed in detail under that heading. Protein losing nephropathy is associated with loss of antithrombin in urine and increased risk of thrombosis in cattle. Similarly, horses with protein-losing enteropathy have low plasma concentrations of antithrombin, which could contribute to the thrombotic tendency noted in these animals.\textsuperscript{30} 

\textbf{Reduction of vitamin K\textsubscript{1}-dependent clotting factors} II, VII, IX, and X may be complicated by defects in blood coagulation and platelet disorders depending upon the infection. In many instances coagulation defects are a manifestation of early disseminated intravascular coagulation. Clinically, petechial and ecchymotic hemorrhages associated with septicaemia are most obvious in the mucous membrane of the mouth, vulva and conjunctiva or in the sclera but they are widely distributed throughout the body on postmortem examination. Diseases causing vasculitis include:

- Systemic viral diseases: equine viral arteritis, equine infectious anemia, African horse sickness, malignant catarrhal fever, bovine ephemeral fever, bovine virus diarrhea, bluetongue, hog cholera, swine fever, equine herpesvirus-1 myeloencephalopathy
- Chlamydial and rickettsial diseases: Anaplasma phagocytophila
- Bacterial diseases: salmonellosis, Histoplasmus capsulatus infection, Actinobacillus pleuropneumonia infection, pasteurellosis, erysipelas in pigs
- Miscellaneous: aspergillosis, Strongyloides vulgaris infection

\textit{Purpura hemorrhagica} 
This is a hemorrhagic disease of horses associated with a leukocytoclastic vasculitis. The majority of cases occur as a sequel to strep. Cases also occur following immunization against Streptococcus equi and as a sequel to infection with other streptococci. The disease appears to be an immune complex-mediated disease with deposition of IgA-containing immune complexes on vessel walls.\textsuperscript{27,28} Hemorrhagic tendencies in the disease include petechial and ecchymotic hemorrhages but also may result in large extravasations of blood and serum into tissues. The hemorrhage and exudation of serum may result in anemia and a depression in the circulating blood volume. Hemorrhage associated with purpura is usually treated with blood transfusions and corticosteroids. A fuller description of the syndrome is given elsewhere.

\textbf{Necrotizing vasculitis} 
Of unknown etiology but possibly immune mediated, this syndrome occurs in all species.\textsuperscript{29} It is similar to purpura and may be local or generalized with petechial hemorrhage and serosanguineous exudation subcutaneously and into tissue spaces. Hemorrhagic tendencies associated with vasculitis may be confused with those associated with a defect in the clotting mechanisms as the primary cause. Differentiation depends on accurate laboratory examination.

\textbf{Treatment} 
Treatment of vasculitis centers on removal of the inciting cause and minimizing or eliminating inflammation in the vessel. Disease-specific treatments are discussed under each of those topics. Inflammation can be reduced by administration of glucocorticoids, the selection and dose of which vary with species (see Formulary in the Appendix). General supportive treatment can include the administration of blood or plasma if severe anemia or hypo-proteinemia occur.

\textbf{Coagulation defects} 
Coagulation defects can be either acquired or inherited. Acquired defects are usually related to exposure to compounds that interfere with production of clotting factors, or that cause depletion of these factors. Inherited defects usually present in young animals, but defects that only marginally increase clotting time might not be detected until the animal undergoes surgery or suffers trauma. Demonstration of defects in blood clotting is based on observation of signs of excessive hemorrhage, with confirmation achieved by measurement of bleeding time and laboratory examination of the activity or concentration of soluble blood clotting factors.

\textbf{Acquired hemostatic defects} 
Acquired clotting defects include those associated with intoxications that impair production or function of clotting factors, and those related to depletion of clotting factors. Disseminated intravascular coagulation is a common cause of hemorrhagic diathesis in animals that is discussed in detail under that heading. Protein losing nephropathy is associated with loss of antithrombin in urine and increased risk of thrombosis in cattle. Similarly, horses with protein-losing enteropathy have low plasma concentrations of antithrombin, which could contribute to the thrombotic tendency noted in these animals.\textsuperscript{30} 

\textbf{DISEASES CAUSING HEMORRHAGE} 

\textbf{Vasculitis} 
Septicemic and viremic diseases 
The vasculitis is associated with endothelial damage occurring as a direct result of infection of the endothelium (e.g. equine herpesvirus-1 myeloencephalopathy, African horse sickness) or from immune-mediated events centered on the endothelium (e.g. purpura hemorrhagica). 

Coagulation defects can be either acquired or inherited. Acquired defects are usually related to exposure to compounds that interfere with production of clotting factors, or that cause depletion of these factors. Inherited defects usually present in young animals, but defects that only marginally increase clotting time might not be detected until the animal undergoes surgery or suffers trauma. Demonstration of defects in blood clotting is based on observation of signs of excessive hemorrhage, with confirmation achieved by measurement of bleeding time and laboratory examination of the activity or concentration of soluble blood clotting factors.

Acquired hemostatic defects 
Acquired clotting defects include those associated with intoxications that impair production or function of clotting factors, and those related to depletion of clotting factors. Disseminated intravascular coagulation is a common cause of hemorrhagic diathesis in animals that is discussed in detail under that heading. Protein losing nephropathy is associated with loss of antithrombin in urine and increased risk of thrombosis in cattle. Similarly, horses with protein-losing enteropathy have low plasma concentrations of antithrombin, which could contribute to the thrombotic tendency noted in these animals.\textsuperscript{30} 

\textbf{Reduction of vitamin K\textsubscript{1}-dependent clotting factors} II, VII, IX, and X may result from coumarol poisoning following ingestion of coumarol containing plants such as Melilotus alba, Anthoxanthum odoratum, Apium nodiflorum, Ferula communis (giant fennel) or warfarin, brodifacoum and related compounds.\textsuperscript{31-33} This syndrome is discussed in detail under each of those headings Vitamin K deficiency, other that induced by intoxication with the compounds listed above and the disorder in postweaned
pigs discussed below, has not been reported in farm animals, probably because forage contains high concentrations of this compound.

A hemorrhagic syndrome in post-weaned pigs is recorded from the USA, New Zealand, France, Japan, Germany, Brazil and South Africa. The syndrome occurs as an outbreak with anemia, hemarthrosis, spontaneous hemorrhage under the skin of the legs and body and hemorrhage following management procedures such as castration. There is a high case fatality and the syndrome is particularly common in pigs a few weeks after weaning. There is prolongation of the prothrombin time and activated partial thromboplastin time. The outbreaks resolve promptly following the injection of vitamin K or its inclusion in the diet. An association has been made with housing on mesh floors. The disease is believed to be due to a deficiency of vitamin K in the diet coupled with housing that precludes intake of vitamin K from the feces or bedding and decreased synthesis in the gut as a result of antibiotics in the feed, especially sulfonamides.

Snake venom may have procoagulant or anticoagulant action. In both cases coagulation defects may occur as procoagulant toxins result in the activation, consumption and depletion of prothrombin and fibrinogen, leading to a coagulopathy, prolonged clotting times and epistaxis.

Carass hemorrhage or blood splash in slaughter lambs has been associated with extended prothrombin times because of prior grazing of coumarin-producing plants. The method of electrical stunning at slaughter lambs can also result in carass hemorrhage.

Paraflaria boviscata produces large extravasations of blood under the skin of cattle and to some extent in tissue spaces. Bleeding from the skin may be the presenting sign of infestation.

A number of fungal toxins can cause hemorrhagic disease when ingested:

- Aflatoxins produced by Aspergillus spp. do so in association with increased prothrombin time in cattle, swine and horses
- Trichothecene toxins produced by fungal infestations of feed by Fusarium spp., Myrothecium spp., Cephalosporium spp.
- Trichothecium spp. also produce hemorrhagic disease
- Toxins associated with Penicillium rubrum
- Grass nematodes that infest Lolium rigidum.

Hydroxyethyl starch solution (Hemastarch), used to increase plasma oncotic pressure in animals with hypoprothrominemia, prolongs cutaneous bleeding, prothrombin and activated partial thromboplastin times and decreases fibrinogen concentration and von Willebrand antigen and factor VIII:C activities in ponies, apparently by dilution of clotting factors.

Navel (umbilical) bleeding in newborn piglets is a syndrome of unknown etiology. Following birth and for periods up to 2 days afterwards, blood drips or oozes from the umbilicus of affected pigs to produce severe anemia, with death frequently occurring from crushing. The navel cords are abnormally large and fleshy and fail to shrink after birth. The defect appears to be one of immaturity of collagen so that a proper platelet clot does not form. Ear-notching for identification is also followed by excessive bleeding. A variable number of piglets within the litter may be affected and the syndrome may have a high incidence on certain problem farms. The addition of vitamin K and folic acid to the sows' ration may be beneficial. Ear-notching for identification has been shown no effect. Vitamin C given to pregnant sows for at least 6 days before farrowing appears to prevent the syndrome.

Jejunal hemorrhage syndrome in cattle is discussed in Chapter 5.

Infestation of sheep by Fasciola hepatica shortens activated partial thromboplastin time and prolongs prothrombin and thrombin times.

Inherited or congenital defects in hemostasis

Hemophilia A

Factor VIII:coagulant (VIII:C) deficiency, hemophilia A, is recorded in Thoroughbreds, Standardbreds, Arabian and Quarter horse colts and sheep and is associated with a deficiency in factor VIII. The disease in the Quarter horse colt also involves deficiency of factors IX and XI. It is inherited as a sex-linked recessive trait with the defective gene located on the X chromosome. Clinically affected foals show signs of a hemorrhagic tendency within a few weeks of birth, with the development of hematomas, persistent nasal bleeding, bleeding from injection sites and sudden death from massive internal hemorrhage. Affected foals are anemic. The diagnosis is made by finding the very low plasma factor VIII:C activity (usually < 10% of values in unaffected animals). Treatment requires fresh frozen plasma or plasma concentrates but is not recommended because of the unavailability of sufficient plasma concentrates, the recurrent nature of the problem and the poor prognosis for long-term soundness.

Von Willebrand disease (factor VIII:vWF deficiency)

Von Willebrand factor is a large adhesive glycoprotein that mediates adhesion of platelets to exposed subendothelium and that also is a carrier for coagulation factor VIII, protecting it from degradation in the circulation. There are three variations of von Willebrand's disease—types I, II and III. Two variations of von Willebrand's disease are recorded in pigs—the simple autosomal recessive trait. The disease in pigs is used as an experimental model for the disease in humans and the pig gene for von Willebrand factor is similar in size and complexity to its human counterpart, with affected pigs having a point mutation within the vWF gene. Type I von Willebrand's disease occurred in an 8-day-old Quarter horse colt that was examined because of extensive purpura. The colt had a concentration of von Willebrand factor that was 9% of that of normal horses. The dam of the colt also had prolonged bleeding time and a concentration of von Willebrand factor 30% of that of normal animals, suggesting a familial and possibly heritable trait. Type II von Willebrand's disease is recorded in a Quarter horse with hemorrhage associated with trauma, prolonged bleeding, lasting several hours, at an injection site, and spontaneous conjunctival hemorrhage, and in a Thoroughbred mare and her colt. The hemorrhage in the Thoroughbred mare and foal was not life-threatening. Type III von Willebrand's disease is usually associated with low concentrations of factor VIII. Suspect factor VIII deficiency has been reported in Hereford calves. The prime manifestation was death shortly following castration with bleeding from the surgical site, intra-abdominal hemorrhage and severe anemia. The disease also occurs in sheep, and is linked to the X chromosome.

Diagnosis is based on the observation of prolonged bleeding after minor trauma or surgery, prolonged activated partial thromboplastin time, although this can be minimal, normal prothrombin time, and decreased factor VIII:C activity and von Willebrand antigen concentration. The ristocetin cofactor activity of von Willebrand factor is reduced in animals with type II von Willebrand's disease. An ELISA is available that is suitable for use in a number of species, including horses, pigs and cattle. Chromogenic assays of factors VII, VIII:C, IX and X developed for testing of human plasma are reliable when used for testing of horse plasma. Desmopressin increases the release of von Willebrand factor from vascular endothelium and is used for
treatment of the disease in humans. There are no reports to date of its use in farm animals or horses. The disease can be managed by housing to minimize trauma and administration of plasma before elective surgery, although this did not completely prevent excessive bleeding.

Factor XI deficiency
Factor XI deficiency is recorded in Holstein-Friesian cattle in Canada, and in Great Britain. It is transmitted as an autosomal recessive gene and occurrence in Britain has been traced to the importation of Canadian semen, with genetic links between carriers in the two countries. Heterozygous cattle have decreased levels of factor XI but are usually asymptomatic. The severity of clinical disease varies in homozygous cattle but they usually show prolonged or repeated bleeding episodes after trauma such as dehorning and hemorrhage following venepuncture. There are occasional deaths associated with multiple hemorrhages. Heterozygote carriers have decreased factor XI coagulant activity but measurement of factor XI activity is not a sensitive test for the carrier status, and a DNA-based test is available that accurately identifies heterozygotes.

Other clotting factor disorders
Prekallikrein deficiency is recorded in a family of miniature horses. The condition was not associated with clinical disease in these horses but blood samples failed to clot. It has also been recorded in three Belgian horses and was detected in this group because one hemorrhaged following castration. The mode of transmission is not known, but the familial nature of the disease suggests that it is heritable.

Heritable fibrinogen deficiency was found in a Border Leicester lamb manifest with inflammation and bleeding at the umbilicus and ear tag wound at 7 weeks of age and in Saanen goats.

Platelet disorders
Disorders of platelets include alterations in the number of platelets in blood (thrombocytopenia or thrombocytopathy) and their function (with reduced function referred to as thrombasthenia). The physiology of platelets varies in important ways among the farm animal species. For instance, aggregation of platelets from horses, but not cattle, is inhibited by aspirin (acetylsalicylic acid), and horse platelets adhere to immobilized autologous fibrinogen while those of sheep do not. Platelets of different species respond differently to some agonists of platelet aggregation, such as ristocetin.

Thrombocytopenia
Clinical signs associated with thrombocytopenia or thrombasthenia are petechial and ecchymotic hemorrhages, prolonged bleeding after venipuncture or from injection sites, epistaxis, hyphema and melena. A combination of some or all of these clinical signs is referred to as purpura. Thrombocytopenia can result from decreased production of platelets in the bone marrow or by increased consumption, increased peripheral destruction or a combination of these factors.

Decreased platelet production is commonly associated with disorders that impair bone marrow function and there is usually simultaneous suppression of granulocyte and erythrocyte production. Thrombocytopenia and neutropenia develop before anemia because of the short life span of these cells relative to erythrocytes.

Increased consumption also occurs with severe trauma and disseminated intravascular coagulation, both of which increase the rate at which platelets are incorporated into clots.

Pseudothrombocytopenia occurs as a result of aggregation of platelets after collection into a glass tube containing EDTA. Ex-vivo aggregation can occur with other anticoagulants, including heparin. This situation can be recognized by the presence of abnormally low platelet counts in animals without evidence of excessive hemorrhage, or by the presence of clumps of platelets on microscopic examination of blood smears. Collection of blood into an anticoagulant other than EDTA or heparin, such as citrate, and measurement of a normal platelet count confirms the diagnosis of pseudothrombocytopenia.

Differentiation of the causes of thrombocytopenia is by clinical examination to detect underlying disease, hematology, examination for anti-platelet antibody and examination of bone marrow aspirates.

Decreased production
Thrombocytopenia due to decreased production, as opposed to increased destruction within the marrow, usually occurs with granulocytopenia because of the short intravascular half-life of both granulocytes and platelets. This occurs with poisonings by Peridium spp. (bracken fern) or Chelanthus seiberi in cattle; the fungus Stachybotrys spp. (which produces a trichothecene) in cattle, pigs, sheep and horses; chronic furazolidone poisoning in calves; poisoning caused by trichloroethylene-extracted soybean meal; drugs that cause bone-marrow suppression, and radiation injury.

Severe myelophthisis, such as is associated with myeloid dysplasia or myelofibrosis, causes thrombocytopenia in association with anemia and leukopenia. A familial myelofibrosis is reported in pygmy goats with anemia, granulocytopenia and thrombocytopenia.

The syndrome is predominantly one of spontaneous hemorrhage but is complicated by bacteremia and fulminant infections facilitated by severe leukopenia. A granulocytopenic syndrome of unknown origin, occurring in all ages of cattle and manifest with a severe hemorrhagic diathesis, high morbidity and high case fatality, has been reported on various occasions in Australia.

Familial diseases resulting in thrombocytopenia secondary to decreased production are recorded in Standardbred horses in which there is generalized bone marrow hypoplasia. Pancytopenia secondary to bone marrow aplasia is reported in a Holstein heifer.

Increased destruction
Inflammation and infection The most common causes of thrombocytopenia are severe gastrointestinal disease (strangulating intestinal obstruction, anterior enteritis, colitis) and infectious and inflammatory disease, where a combination of increased destruction and increased consumption is the cause.

Infection by a variety of viral, bacterial or rickettsial agents causes mild to severe thrombocytopenia. African horse sickness, equine infectious anemia, Anaplasma phagocytophila (equine granulocytic ehrlichiosis) and infection by Neorickettsia risticii (Potomac horse fever) cause mild to moderate thrombocytopenia.

Infection such as occurs in hog cholera and African swine fever can result in thrombocytopenia and contributes to the hemorrhagic tendency seen in these diseases. Outbreaks of hemorrhagic disease due to thrombocytopenia in veal calves have been attributed to infection with bovine virus diarrhea (BVD) virus type 2 and the disease has been reproduced experimentally with noncytopathic BVD virus.

The appearance of hemorrhage was directly related to the number of circulating platelets and bleeding was seen when platelet numbers fell below 500/mL. Calves that developed thrombocytopenia had low (+ 1:32) BVD neutralizing titers. The virus infects megakaryocytes. Thrombocytopenia with a bleeding tendency (bloody diarrhea, petechial and ecchymotic hemorrhage) is also recorded in approximately 10% of adult cattle with acute BVD infection.

Infection by Theileria annulata causes thrombocytopenia and prolonged
Horses of any age can be affected. The cause is usually not identified but the disease can be associated with administration of drugs, especially penicillin. The disease is caused by binding of IgG to platelets or to megakaryocytes, with subsequent impaired maturation, enhanced clearance or both, resulting in low platelet counts in blood. Petechiation and hemorrhage may be confined to single systems, such as the respiratory system with epistaxis and hematomas in the nasal sinuses, or the genital tract producing a bloody vulval discharge, with no detectable abnormality at other mucous membranes. More generalized involvement with widespread petechiation of mucous membranes, epistaxis and melena can also occur. Diagnosis is by measurement of blood platelet concentration and elimination of disseminated intravascular coagulation or primary diseases. Demonstration of platelet-surface-bound IgG on a significant proportion of platelets is diagnostic. Fewer than 0.15% of platelets from normal horses have IgG bound to the surface, whereas more than 4% of platelets of thrombocytopenic horses have IgG on the surface. Treatment includes the immediate removal from any medication and the administration of dexamethasone (0.040 mg/kg intramuscularly, intravenously or orally, once daily) or prednisolone (1 mg/kg orally), but not prednisone. This is usually effective in restoring platelet count and controlling hemorrhage. Resolution of hemorrhage can occur even before there are marked changes in platelet count. Treatment might need to be continued for days to weeks. Most horses do not require long-term treatment. For horses with life-threatening hemorrhage, administration of platelet-rich plasma or blood is needed. A transfusion volume of 10 mL blood per kg BW can be effective. Successful treatment with aspirin in horses that do not respond to glucocorticoids is reported (0.5–1.5 mg/kg orally every 24 h). Splenectomy has been used to treat horses with chronic, idiopathic thrombocytopenia that is refractory to medical therapy. However, surgical treatment should be undertaken only in extreme cases, and with attention to the effect of thrombocytopenia on hemostasis during surgery.

Thrombocytopenia in adult animals with normal prothrombin times and partial thromboplastin times and with no evidence of disseminated intravascular coagulation is considered most likely to develop by autoimmune-mediated mechanisms. Immune-mediated thrombocytopenia can be induced by drugs or can be secondary to infectious or neoplastic disease but most cases are idiopathic. The disease is reported most commonly in horses but does occur in cattle.
Thoroughbred filly with excessive hemorrhage after pin firing. The filly had prolonged bleeding time and normal clot retraction. The filly’s platelets did not bind to collagen and the defect was deduced to be in calcium signaling within the platelets.99

**Thrombocytosis**

Thrombocytosis is not usually associated with purpura or a tendency to hemorrhage unless the platelets have abnormal function. Thrombocytosis is considered to be either primary or secondary.100,101 Primary thrombocytosis is a result of excessive production of megakaryocytes in the absence of any inciting disease or increased release into the circulation. While exercise, epinephrine and vincristine can increase platelet counts, the most important cause of primary thrombocytosis is myeloproliferative disorder resulting in abnormal rate of platelet production. Primary thrombocytosis is rare in farm animal species.

Secondary thrombocytosis occurs in animals with severe systemic inflammatory or infectious diseases of more than several days duration, and usually of several weeks duration. Young animals appear to be more susceptible but the condition can occur in animals of any age. Detection of thrombocytosis should prompt a thorough clinical examination for a cause of chronic inflammation in the animal. Common causes in horses include pneumonia, *Rhodococcus equi* infection, septic arthritis and colitis.97 Thrombocytosis with Heinz body anemia is reported in cattle fed cabbage.

**Disseminated Intravascular Coagulopathy and Hypercoagulable States**

There is increasing recognition that abnormalities in blood clotting and fibrinolysis exist in both subclinical and clinical forms in many diseases of farm animals, and that the presence and severity of these disorders is related to prognosis for survival. There is a spectrum of abnormalities ranging from mild changes in concentration or activity of clotting factors and indicators of fibrinolysis, through evidence of excessive coagulation or impaired fibrinolysis, to a hemorrhagic diathesis. Previously, the most extreme form of this disorder was recognized as a hemorrhagic diathesis and termed disseminated intravascular coagulation (DIC). Increasing sophistication and availability of measures of coagulation and fibrinolysis have revealed that abnormalities of hemostasis exist even in animals without clinical evidence of excessive hemorrhage. These milder changes in hemostasis and fibrinolysis are, not surprisingly, much more common than is DIC, but are still associated with an increased case fatality rate.

**Etiology and Epidemiology**

DIC and hypercoagulable states are acquired disorders of hemostasis in animals that occur as a consequence of severe disease that induces systemic inflammation (systemic inflammatory syndrome). DIC is now regarded as a component and consequence of systemic inflammation, rather than being an isolated disorder of hemostasis.100 DIC and hypercoagulable states are therefore associated with any severe disease that initiates a systemic inflammatory response. A partial listing is: colitis, enteritis, infective lesions of the intestines, septicaemia, abomasal torsion, metritis, severe trauma, immune-mediated inflammation (e.g. purpura hemorrhagica), hyperthermia and neoplasia. A common, but not universal feature, of diseases that induce DIC or a hypercoagulable state is the presence of presumed or documented endotoxaemia, although DIC can be induced by most infectious organisms. It is important to recognize that any severe disease that causes a systemic inflammatory response can incite changes in hemostatic function.

The presence of a hypercoagulable state or DIC is most well recognized in horses with gastrointestinal disease.10,102-104 It also occurs in cattle with abomasal displacement and in endotoxic calves.105,106 Low plasma antithrombin concentrations occur in cows with hepatic disease.107 The disease has been reproduced experimentally in pigs, and probably occurs naturally in that species in many diseases, including African swine fever.108,109 The prevalence of DIC (clinically evident hemorrhage) is uncommon, while the prevalence of a hypercoagulable state detectable only by clinicopathologic testing is much more common.10,104

The prevalence of the syndrome is not well defined, partly because of problems in achieving a confirmatory diagnosis by laboratory assessment of factors involved in coagulation or fibrinolysis because of the lack of laboratories providing the necessary assays, and partly because of lack of recognition of the disease. Five of 20 cattle with either left or right displacement of the abomasum had a hypercoagulable state.106 Of horses examined at a referral institution for colic, 3.5% had clinical signs consistent with DIC and supportive laboratory evidence.110 All these horses had severe inciting disease, with most requiring surgical intervention for infective intestinal disease. This study probably under-represents the proportion of horses with severe gastrointestinal disease that have hemostatic abnormalities, given that many horses with severe gastrointestinal disease have subclinical abnormalities in hemostasis and fibrinolysis.30 The survival rate among horses with colic and DIC or a hypercoagulable state was 19%, whereas that in horses with colic but no clinicopathologic evidence of a hemostatic disorder was 80%.102 Twelve of 37 horses with colitis had clinicopathologic evidence of a hypercoagulable state, although none had clinical signs of DIC at the time of sample collection.30 Of the 12 horses with a hypercoagulable state, five died, compared to two of 25 horses with colitis that did not have evidence of a coagulopathy.

Clinically relevant alternations in hemostatic and fibrinolytic indices occur in neonatal foals with septicemia.111 Derangements in hemostatic or fibrinolytic indices were helpful in identification of septic foals with increased risk of coagulopathy, but were not helpful in predicting hemorrhage as compared to thrombus formation. Twenty-three of the 34 septic foals did not survive. Survival of septicemic foals was correlated with Gram-negative bacteremia but not with the presence of endotoxin or coagulopathy.111

**Prognosis**

The prognosis for animals with clinical signs of disseminated coagulation is very poor. Horses without physical signs of hemorrhage or defective fibrinolysis but with clinicopathologic evidence of a hypercoagulable state have a worse prognosis than horses without evidence of a hypercoagulable state.10,30,103-104 When evaluating the prognosis of an animal with evidence of a coagulopathy as part of the systemic inflammatory syndrome it must be borne in mind that the coagulopathy is secondary to the initiating disease; the more severe the initiating disease the greater the likelihood that the animal will have a coagulopathy, and the more severe the initiating disease the poorer the prognosis. DIC and lesser abnormalities of hemostasis can therefore be regarded as markers of disease severity and considered accordingly when determining a prognosis. This is not to minimize the importance of DIC and hemostatic defects of lesser severity in the pathogenesis of severe disease, and the need to institute effective preventive measures and treatment.

**Pathophysiology**

DIC, or consumption coagulopathy, can develop in a number of diseases which, in themselves, are not diseases that primarily affect hemostatic mechanisms. The pathogenesis involves systemic activation of coagulation with intravascular deposition...
of fibrin leading to thrombosis of small and medium-sized blood vessels with subsequent organ failure. Depletion of platelets as a result of platelet activation and binding to fibrin to form clots, and of coagulation factors, results in excessive bleeding. The systemic formation of fibrin results from increased generation of thrombin and the simultaneous suppression of anticoagulation mechanisms (which are detectable in animals as reduced concentration of antithrombin) and impaired fibrinolysis.\textsuperscript{112} Products of fibrinogen activation, including fibrinopeptides A and B, contribute to systemic vasoconstriction and the hypoperfusion of some organs. The disorder, in its most extreme form, involves both excessive coagulation and, seemingly paradoxically, bleeding.

Systemic activation of coagulation is part of the systemic inflammatory response syndrome, which is dominated by interleukins 1 and 6 and tumor necrosis factor-alpha.\textsuperscript{108,112} There might be a contribution of complement activation to the hypercoagulability. Activation of clotting occurs through either damage to endothelium or activation and release of tissue factor. Tissue factor expression is increased by one or more of the pro-inflammatory cytokines (interleukin-1, -6, -8, and tumor necrosis factor), which are almost universally increased in diseases that feature systemic inflammation. Generation of tissue factor results in activation of the extrinsic clotting cascade with resultant increases in thrombin. The increased activity of the coagulation cascade is temporally associated with impaired activity of anticoagulant mechanisms, demonstrable as decreases in plasma concentration of antithrombin and protein C. Further exacerbating the effect of increased rate of fibrin synthesis is impaired fibrinolysis, indicated by diminished activity of plasminogen and increased activity of plasminogen-activator inhibitor.\textsuperscript{112}

In summary DIC is a hemorrhagic diathesis, characterized by an augmentation of normal clotting mechanisms that results in depletion of coagulation factors, deposition of fibrin clots in the microvasculature and the secondary activation of fibrinolytic mechanisms. The augmentation of clotting mechanisms can result in a depletion of platelets and factors V, VIII, IX, XI and XIIa, and the depletion of fibrinogen in association with the formation of fibrin clots in the microvasculature. These fibrin clots decrease tissue perfusion, which can then lead to further activation and depletion of clotting factors by the release of tissue thromboplastin as a result of tissue hypoxia. The bleeding tendency occasioned by the depletion of these clotting factors is further accentuated by the secondary activation of the thrombotic system with the production of fibrin degradation products that have anticoagulant properties.

Impaired capacity of the monocyte phagocytic system contributes to the disease. Macrophages in the reticuloendothelial system remove fibrin degradation products and activated clotting factors from the circulation. Loss or diminution of the capacity to remove hemostatic and fibrinolytic compounds causes increases in plasma concentration of these products and exacerbation of the disease. Damage to the reticuloendothelial system, notably in the liver and spleen, resulting from damage as a consequence of the underlying disease (endotoxemia) or lack of perfusion of liver and spleen as part of DIC, decreases removal of these compounds and induces a viscous cycle of disease.

DIC can be initiated by a variety of different mechanisms.

- Extensive tissue necrosis, such as occurs in trauma, rapidly growing neoplasm, acute intravascular hemolysis and infective diseases such as blackleg, can cause extensive release of tissue thromboplastin and initiate exuberant coagulation via the extrinsic coagulation pathway.

- Exuberant activation of the intrinsic pathway can occur when there is activation of the Hageman factor by extensive contact with vascular collagen, as occurs in disease with vasculitis, or those associated with poor tissue perfusion and tissue hypoxia with resultant endothelial damage.

- Factors that initiate platelet aggregation, such as endotoxin, that cause reticuloendothelial blockage, such as excessive iron administration to piglets, or that cause hepatic damage to interfere with clearance of activated clotting factors, can contribute to the occurrence of disseminated intravascular coagulation.

**CLINICAL SIGNS**

As discussed above, defects in hemostasis and fibrinolysis range from those that are detectable by clinicopathologic examination but are not associated with clinical signs of excessive bleeding or coagulation, through fulminating hemorrhagic diathesis. The presence of a hypercoagulable state that is not associated with signs of excessive bleeding or thrombosis nonetheless worsens the prognosis of severe diseases. This is probably due to DIC-induced injury to organs that is not detectable against the background of damage caused by the primary disease but that has an important or pivotal effect on the animal's well being. The next progression of the disease is evidence of enhanced thrombosis, most evident as thrombosis of large vessels after minor damage such as that associated with intravascular catheterization or simple venipuncture. In some cases vessels can thrombose without obvious inciting cause. An example of a common manifestation of this stage of the disease is jugular vein thrombosis in horses or cattle with severe disease and low plasma concentration of antithrombin.\textsuperscript{30,107}

An unusual, but severe, manifestation of DIC in horses is thrombosis of the distal limbs, resulting in ischemic necrosis of the limb and death of the animal. This clinical manifestation of DIC occurs in foals and, to a lesser extent, in adults with evidence of septicemia or severe gastrointestinal disease.\textsuperscript{113}

The most severe acquired hemostatic defect in animals with systemic disease is DIC. This extreme of the clotting disorder is manifested by local or generalized bleeding tendencies that vary in severity from occurrence of petechial hemorrhages in mucous membranes to life-threatening hemorrhage or infarction of organs. Ischemic damage to a wide variety of organs is possible, with the gastrointestinal tract and kidneys being commonly affected.\textsuperscript{49}

**CLINICAL PATHOLOGY**

There are a large number of hemostatic and fibrinolytic factors that can be measured in research laboratories, only a few of which are routinely available in clinical laboratories. The following measures are commonly used to detect hypercoagulable states or DIC in clinical situations:

- Platelet count. The abnormality consistent with DIC is thrombocytopenia.
- Prothrombin time. This is usually prolonged in animals with DIC but can occasionally be shortened in animals with a hypercoagulable state.
- Activated partial thromboplastin time. This measure of hemostasis is usually prolonged in animals with coagulopathies.
- Serum markers of fibrinogen activation/fibrin degradation. FDPs have poor sensitivity and specificity for detection of DIC. Plasma D-dimer concentration is more sensitive for detection of abnormalities in hemostatis/fibrinolysis.
- Fibrinogen concentration. Classical descriptions of DIC include...
A number of studies provide detailed description of the occurrence, and time course, of abnormalities in hemostatic and fibrinolytic function in horses with gastrointestinal disease. The general pattern is that of prolonged clotting times (prothrombin (PT), activated partial thromboplastin (aPTT)) with diminished activity of antithrombin and protein C, and increased plasma concentrations of fibrinogen and fibrin degradation products. D-imer concentrations have been reported to increase in horses undergoing surgery for colic or to be lower in horses with colic than in healthy horses. Platelet concentration is reduced in horses with colic and evidence of coagulopathy. Abnormalities in hemostatic factors are more common in peritoneal fluid than in blood of horses with colic. Tissue plasminogen activator, plasminogen, protein C, antithrombin III, and alpha-2-antiplasmin activities and concentrations of fibrinogen and fibrin degradation products are greater in peritoneal fluid from horses with colic than in peritoneal fluid of healthy horses.

Compared to healthy foals, the PT, aPTT and whole blood recalcification times are significantly longer in septic foals. The fibrinogen and fibrin degradation products concentrations, percentage plasminogen, alpha-2-antiplasmin and plasminogen activator inhibitor activities, and tumor necrosis factor and interleukin-6 activities are greater, and protein C antigen and antithrombin III activity are lower in septic foals. Cattle with displaced abomasum often have abnormalities in one or more of PT, aPTT, thrombin time, platelet count and plasma concentration of fibrin degradation products. Pigs with induced endotoxemia have increases in activity of tissue factor, plasminogen activator and plasminogen activator-inhibitor, and concentrations of thrombin–antithrombin complexes and fibrin monomer, and a decline in fibrinogen and factor VII concentrations.

**NECROPSY EXAMINATION**

It is important to differentiate the abnormalities at necropsy caused by DIC from those of the underlying disease. This can be challenging. The presence of DIC is suspected by the presence of hemorrhage in the carcass. Hemorrhage can vary from occasional petechiation to frank hemorrhage into body cavities. Horses dying of DIC usually have widespread lesions, including petechiation of mucosal and serosal surfaces, including the mesentery and pleura. There is often hemorrhage into parenchymatous organs (kidneys, adrenals), lungs and the myocardium, and infarcts in the adrenals and kidney. Microthrombi are detectable in the intestine and kidney of some horses with DIC.

**DIAGNOSTIC CONFIRMATION**

The presence of a hypercoagulable state is determined by clinicopathological testing. DIC is diagnosed by the presence of clinical signs of a hemorrhagic diathesis and laboratory confirmation of abnormalities in hemostasis and fibrinolysis. A conventional definition of DIC requires the presence of clinical evidence of coagulopathy and the presence of at least three abnormal measures of coagulation or fibrinolysis. It is likely that this definition will change as our understanding of the spectrum of abnormalities and manifestations of the disorder matures.

Differential diagnoses include all of the acquired or inherited coagulopathies. However, the cardinal differentiating attribute of DIC or the lesser hypercoagulable states is the presence of severe inciting disease.

**TREATMENT**

Most recommended therapies for DIC have been extrapolated from the human literature and may not be applicable to farm animals. However, generally stated, the principles of therapy are:

- Treatment of the underlying disease and correction of acid–base, inflammatory, electrolyte and perfusion abnormalities
- Restoration of normal activity or concentration of clotting factors in blood
- Halting or attenuating the increased coagulopathy
- Minimizing effect of microthrombi and thrombi on organ function.

Disseminated intravascular coagulation is invariably secondary to an initiating primary disease. Vigorous therapy should consequently be directed toward correction of the primary initiating disease. Aggressive intravenous fluid administration to maintain tissue perfusion and to correct any acid–base and electrolyte imbalance is also very important. There should be aggressive treatment of endotoxemia and of diseases likely to induce endotoxemia. Treatment of endotoxemia is discussed elsewhere in this text, and current reviews are available.

The plasma concentration of clotting factors should be restored, or supplemented, in horses with clinical or clinicopathological evidence of a coagulopathy. The practice of blood component therapy is well accepted in human medicine but because of technological limitations is not generally available in farm animals. However, stored plasma, preferably fresh frozen, can be administered to increase the concentration of clotting factors that are depleted during hypercoagulable states or DIC. Antithrombin is often readily measured and horses with low plasma antithrombin activity should be administered plasma. The dose of plasma necessary to increase blood antithrombin activity to appropriate levels has not been determined. However, many clinicians use a plasma antithrombin activity 60% of that of healthy horses as a minimal acceptable activity. This choice has not been verified empirically. Dosages of plasma vary from 2–10 mL/kg, intravenously. Platelet-rich plasma, or whole blood, can be used to treat thrombocytopenia.

Heparin and low-molecular-weight heparin is used to treat horses with hypercoagulable states and its use is discussed above. The aim is to prevent formation of thrombi and microthrombi. Heparin requires antithrombin as a cofactor, and it might not exert its full therapeutic activity in horses with abnormally low blood antithrombin concentrations.

Aspirin is used to inhibit platelet activity in horses with prothrombotic states. Its efficacy in reducing morbidity or mortality has not been determined.

**REFERENCES**

anisms discussed above under Disseminated intravascular coagulopathy. Thrombosis of the jugular vein is discussed elsewhere. Primary diseases involving thrombosis are thromboembolic colic in horses and aortoiliac thrombosis in horses.

An apparently primary defect in protein C activity in a Thoroughbred colt with a hypercoagulable state has been described.1 The colt had repeated episodes of venous thrombosis and developed renal failure. Plasma concentrations of protein C were within the reference range for healthy horses, but the activity of protein C in plasma was 32% of that of healthy horses, suggesting a defect in the protein.

REFERENCE

Disorders of red cell number or function

ANEMIA

Synopsis

Etiology Deficiency of circulating erythrocytes associated with hemorrhage, increased destruction or the inefficient production of erythrocytes. There are a large number of specific etiologies.

Epidemiology Specific to the underlying cause of the anemia

Clinical findings Pallor of mucosa, tachycardia, lethargy, exercise intolerance, arrhythmia, ileus, decreased ruminations and colic. Petechial and ecchymotic hemorrhages, icterus, hemorrhoglobinuria, bleeding tendencies can be seen if the underlying cause is excessive hemorrhage.

Clinical pathology Examination of erythron, bone marrow and serum total protein for nature and severity of anemia; clinical chemistry for associated organ damage. Specific tests for etiology

Necropsy findings Pallor of tissues.

Diagnostic confirmation Decreased erythrocyte count or packed cell volume

Treatment Treatment of specific etiology. Transfusion of whole blood, packed red cells, or stromal free hemoglobin if the anemia is severe. Corticosteroids for immune-mediated anemias and supportive treatment.

ETIOLOGY

Anemia can be classified as hemorrhagic anemia, hemolytic anemia, or anemia due to decreased production of erythrocytes. Another classification system is based on evidence of regeneration of anemia, with anemia classified as either regenerative or nonregenerative. Both classifications are useful in determining the cause, treatment and prognosis. Diseases causing

THROMBOSIS (HYPERCOAGULABILITY)

Abnormal formation of thrombi is often a consequence of diminished concentrations or activity of anticoagulant factors, such as antithrombin, protein C and antiplasmin, increased concentrations of plasminogen activator–inhibitor or abnormalities of vessel walls. Thrombotic disease is usually a consequence of a primary disease that depletes anticoagulant factors and involves mech-
anemia in horses are listed in Table 25.2 and those causing hemolytic anemia in cattle in Table 20.4.

**Hemorrhagic anemia**
Acute hemorrhage and hemorrhagic shock are discussed in Chapter 2. The diseases discussed here are those that cause normovolemic anemia. While anemia occurs after restitution of plasma volume in animals with severe hemorrhage, most diseases that cause normovolemic anemia do so because of the chronic loss of blood either from the body or into a body cavity. The most common route of loss is through the gastrointestinal tract. Diseases include:

- Parasitism – intestinal nematodiasis: *Teladorsagia circumcincta* or *Haemonchus contortus* in lambs and sheep, *Ostertagia ostertagi* in cattle, *Strongylus* sp. and cyathostomes in horses; nematodiasis including *Fasciola hepatica* in sheep and cattle; hematophagous lice and ticks, including *Linognathus vituli* in calves
- Gastrointestinal disease, including:
  - Abomasal ulceration in cattle (both spontaneous and associated with abomasal lymphoma)
  - Gastric ulceration in horses (anemia is an unusual manifestation of this disease)
  - Gastric squamous cell carcinoma in horses
  - Esophagogastric ulceration in pigs
  - Proliferative enteropathy in pigs (usually a paracutaneous disease)
  - Bleeding from lesions in the small intestine (neoplasia, fungal infection, mural hematoma)
- Respiratory tract:
  - Guttural pouch mycosis in horses
  - Ethmoidal hematoma in horses
  - Caudal vena cava thrombosis and pulmonary embolism in cattle
- Genitourinary tract disease, including:
  - Enzootic hematia in cattle (bladder cancer) and bladder transitional cell tumor (horse)
  - Pyelonephritis
  - Vaginal varicose vein hemorrhage in mares
  - Ureteral lesion and hematia in geldings and stallions
  - Middle uterine artery rupture of mares (usually a paracutaneous disease)
  - Idiopathic renal hematia in horses
  - Hemorrhage into body cavities:
    - Hemangiosarcoma
    - Juvenile bovine angiomatosis
  - Defects in clotting (see 'Diseases causing hemorrhage')
    - Thrombocytopenia
    - Deficiency of clotting factors
    - Umbilical bleeding in piglets.

**Hemolytic anemia**

Cattle and sheep
- Babesiosis, anaplasmosis, *Mycoplasma ovis comb. nov.* (formerly *Eperythrozoon ovis*) eperythrozoonosis, typanosomiasis, nagana, theileriosis, alone or in various combinations
- Bacillary hemoglobinuria
- Leptospirosis (*L. interrogans* serovar *pomona*)
- Bovine virus diarrhea and mucosal disease
- Postparturient hemoglobinuria
- Associated with grazing *Brassica* spp., rape, kale, *chou moellier*, turnips, cabbages
- Associated with the excessive feeding of culled onions or cannery offal, especially tomatoes and onions
- Poisoning by *Mercurialis, Ditaxis, Pinella* and *Allium* spp.
- Poisoning by miscellaneous agents, including phenothiazine, guaifenesin
- Poisoning – chronic copper poisoning. In sheep secondary to pyrrolizidine alkaloids as in toxemic jaundice or primary from the feeding of diets too high in copper. Cattle are much less susceptible than sheep, although preruminant calves are very susceptible
- Treatment with long-acting oxytetracycline
- Water intoxication and drinking cold water in calves, and in goat kids fed water from a nipple bottle
- Inadvertent administration of hypotonic or hypertonic fluids (water, 20% dimethylsulfoxide)
- As a sequel to severe cutaneous burns. The severity of the hemolysis correlates with the amount of skin area burned. Hemolysis is due to oxidative damage of red cell membranes that occurs within minutes of the burn. Prevention and treatment include immediate administration of polyionic fluids to prevent hemolysis and to prevent hemolytic uremia

Horses
- Equine infectious anemia, although the pathogenesis of the anemia is probably multifactorial, including hemolysis and decreased red cell production
- Babesiosis
- Phenothiazine poisoning. This antihelminthic is now used rarely in horses
- Red maple leaf (* Acer rubrum*) toxicity
- Ingestion of dried garlic (> 0.2 g/kg BW) results in development of Heinz bodies and hemolytic anemia
- Intravenous administration of hypotonic or hypertonic fluids (water, 20% dimethylsulfoxide)
- As a sequel to clostridial abscessation. The anemia occurs more than 10 days after development of the abscess and is associated with the presence of IgG or IgM on the surface of red cells
- Alloimmune hemolytic anemia (isoerythrolysis) of foals
- Autoimmune hemolytic anemia
  - Immune-mediated anemia is recorded in calves but is rare. All reported cases have occurred in calves under 6 months of age
  - Immune-mediated anemia can occur in lambs that are fed cow colostrum as a source of immunoglobulin. This is not a common sequel to the feeding of cows' colostrum and occurs only with the colostrum from certain cows. Anemia is evident at 7–20 days of age but jaundice and hemoglobinuria are not usually present. The syndrome must be differentiated from immune-mediated thrombocytopenia, which occurs at a younger age in some lambs fed bovine colostrum
  - Rarely, in adults after vaccination
  - Congenital anemia associated with dyserythropoiesis and accompanied by dyskeratosis and progressive alopecia is recorded in Polled Hereford calves. The anemia is present at birth and the disease is probably inherited
  - A congenital anemia with jaundice is recorded in Murray Grey calves and it is postulated that a defect in the red cell membrane leads to intravascular hemolysis.
- Pigs
  - Eperythrozoonosis is recorded but hemolytic anemia is rare
  - Isoerythrolysis, thrombocytopenia and coagulation defects are dealt with in the previous section
- Generalized cytomegalovirus infection.
The diseases in this group tend to affect specific deficiencies that result in anemia are described:

- Lead intoxication in horses causes mild anemia, but signs of peripheral neuropathy are the more obvious manifestation.
- Abnormalities in red cell function can lead to increased removal of red cells from blood (extravascular hemolysis) and are discussed under 'Abnormalities of red cell function'.

**Anemia due to decreased production of erythrocytes or hemoglobin (nonregenerative anemia)**

The diseases in this group tend to affect all species so that they are divided up according to cause rather than according to animal species.

**Nutritional deficiency**

Nutritional deficiencies impair production of hemoglobin or red cells. A number of specific deficiencies that result in anemia are described:

- Cobalt and copper. These elements are necessary for all animals, but clinically occurring anemia is observed in only ruminants. Copper deficiency induced by zinc toxicity causes anemia in pigs.
- Iron, but as a clinical occurrence this is limited to rapidly growing animals, including baby pigs, young calves designated for the white veal market, housed lambs and foals. This predilection of young animals for iron deficiency is attributable to their rapid growth and hence requirement for relatively large intakes of iron (which, in addition to production of hemoglobin, is used in production of myoglobin and other iron-containing compounds), the low concentration of iron in milk, and management practices that deny access of the animals to pasture or soil from which they can obtain iron.
- Anemia in piglets can be caused by iron deficiency. The disease occurs in both housed piglets and those kept on dirt, although the disease is believed to be less common in those kept at pasture or on dirt, in part because of the availability of iron ingested in dirt.
- Iron deficiency should be considered as a possible cause of failure to perform well in housed calves. Male calves up to 8 weeks of age and on a generally suitable diet can show less than optimum performance in erythron levels, and the calves with subclinical anemia have deficits in growth rate and resistance to diarrhea and pneumonia. Calves fed 20 mg Fe/kg milk replacer develop hypoferremia and mild anemia, whereas those fed 50 mg Fe/kg do not.
- Iron deficiency anemia occurs in housed lambs and is prevented by oral or parenteral supplementation with iron. Anemia and poor weight gain were not prevented in all lambs by a single administration of 330 mg of iron once orally at 1–5 days of age, although there was a marked increase in serum iron concentration. Treated lambs had higher hematocrit and greater weight gain than did untreated lambs.
- Microcytic anemia and hypoferremia occur in Standardbred foals kept at pasture for 12 h/day. These changes are not prevented by oral administration of four oral doses of 248 mg of iron, suggesting that higher levels of supplementation are needed. Conversely, hypoferremia and anemia are reported in stable foals but not in a pasture cohort. The stable foals had clinical signs of anemia (lethargy) and low hematocrit, hemoglobin concentration and serum iron concentration, which were restored to normal values by iron supplementation (0.5 g iron sulfate orally once daily, 3 g of iron sulfate top dressed on cut pasture fed to the foals and their dams, and unlimited access to a lick block containing iron). While colostrum of mares is rich in iron, milk has much lower concentrations, probably explaining the low serum iron of some nursed foals and demonstrating the need for access to iron supplements or, preferably, soil or pasture. Supplemental foals with iron should be undertaken cautiously because of the documented hepatotoxicity of large doses of iron given orally to newborn foals. Toxic hepatopathy develops in newborn foals administered iron fumarate at 16 mg/kg BW within 24 hours of birth, similar to the situation in piglets. Iron supplementation of foals should be done cautiously.
- A great deal of attention is paid to providing adequate iron to racehorses, often by periodic injection of iron compounds regularly during the racing season, or provision of hematinc supplements. Given that strongylosis is all but unknown in race horses in the current era of intensive parasite control programs and stabling of horses, anemia is exceedingly rare in healthy race horses. Supplementation with iron of horses on a balanced, complete ration is therefore unlikely to be necessary. Moreover, administration of excessive iron could be dangerous, although iron toxicity has not been documented in race horses, as it has in foals. Oral administration of 50 mg Fe/kg body weight to ponies for 8 weeks increased serum iron concentration, did not affect hematocrit and did not induce signs of disease.
- Potassium deficiency is implicated in causing anemia in calves.
- Pyridoxine deficiency, produced experimentally, can contribute to the development of anemia in calves.
- Folic acid deficiency is rare in horses, has not been reported as a spontaneous disease in pigs, and is unlikely to occur in ruminants because of the constant production of folic acid by rumen bacteria. Plasma folate acid concentrations vary in pregnant mares kept at pasture, and in their foals, but there is no evidence of folate deficiency in either mares or foals. Administration of antifolate drugs (trimethoprim, sulfonamides, pyrimethamine, methotrexate) could, theoretically, cause folate deficiency in horses. Folate deficiency causing anemia and leukopenia is reported in a horse treated for equine protozoal myelitis with antifolate drugs concurrent with oral supplementation with folic acid. Intravenous administration of folic acid (0.055–0.11 mg/kg BW) resulted in rapid resolution of leukopenia and anemia. paradoxically, oral administration of folic acid in monogastric animals receiving antifolate drugs impairs absorption of folic acid in the small intestine and causes folate deficiency. Administration of folic acid, sulfonamides and pyrimethamine orally to pregnant mares results in congenital signs of folate deficiency in foals, including anemia and leukopenia.

**Chronic disease**

Chronic inflammatory disease causes mild to moderate anemia in all species of large animals. The anemia can be difficult
Disorders of red cell number or function

to differentiate from that of mild iron-deficiency anemia. The genesis of anemia of chronic inflammation is multifactorial and includes sequestration of iron stores such that iron availability for hematopoiesis is reduced despite adequate body stores of iron, reduced erythrocyte life span and impaired bone marrow response to anemia. The result is normocytic, normochromic anemia in animals with normal to increased serum ferritin concentrations. The clinicopathologic features of both iron deficiency anemia and anemia of chronic disease are detailed in Table 9.1.

- Chronic suppurative processes can cause severe anemia by depression of erythropoiesis
- Radiation injury
- Poisoning by bracken, trichloroethylene-extracted soybean meal, arsenic, furazolidone and phenylbutazone, cause depression of bone marrow activity
- A sequel to inclusion body rhinitis infection in pigs
- Porcine dermatitis and nephropathy syndrome
- Intestinal parasitism, e.g. ostertagiasis, trichostrongylosis in calves and sheep, have this effect.2

Red cell aplasia
- Red cell hypoplasia is a fatal syndrome of anemia, immunodeficiency and peripheral gangliopathy that develops at 4–8 weeks of age in some fell pony foals
- Anemia in some horses follows the administration of recombinant human erythropoietin.43-45 The anemia is due to pure red cell aplasia and is manifest as normocytic, normochromic anemia. The disease is attributable to injection of horses with recombinant human erythropoietin with subsequent development of substances in blood, presumably antibodies to rhEPO, that cross-react with and neutralize endogenous erythropoietin in affected horses.43,45 Not all horses administered rhEPO develop anemia, but the disease is reported as an outbreak in a stable of Thoroughbred race horses administered the compound.45 Severely affected horses die. Treatment of severely affected horses is futile, but mildly affected horses can recover.43 Whether the recovery was spontaneous or because of administered glucocorticoids is unknown. Administration of cyclophosphamide and glucocorticoids was not effective in treatment of several severely affected horses. Blood transfusion provides temporary relief

- Pure red cell aplasia not associated with administration of rhEPO occurs but rarely in horses. The disease can be transient.

Myelophthisic anemia
Myelophthisic anemia, in which the bone marrow cavities are occupied by other, usually neoplastic tissues, is rare in farm animals. Clinical signs, other than of the anemia, which is macrocytic and normochromic, include skeletal pain, pathological fractures and paresis due to the osteolytic lesions produced by the invading neoplasm. Cavitation of the bone may be detected on radiographic examination.

- Lymphosarcoma with bone marrow infiltration occurs in most species
- Plasma cell myelomatosis has been observed as a cause of such anemia in pigs, calves and horses
- Infiltration of neoplastic cells, other than lymphoma or myeloma, such as melanoma in horses
- Myelophthisic anemia due to myelofibrosis is reported in a pony and as a familial disease in pygmy goats.

PATHOGENESIS
Anemic hypoxia
The most important abnormality in anemia is the hypoxemia and subsequent tissue hypoxia that results from the reduced hemoglobin concentration and oxygen-carrying capacity of blood. The anemia becomes critical when insufficient oxygen is delivered to tissue to maintain normal function.

Oxygen delivery is described mathematically by the Fick equation:

\[
\text{Oxygen delivery} = \text{cardiac output} \times \text{arteriovenous oxygen content difference}.
\]

Oxygen delivery is therefore the rate at which oxygen is delivered to the tissue — it is a combination of the rate at which oxygen arrives at the tissue in arterial blood and the proportion of that oxygen extracted from the capillary blood.

Cardiac output is determined by heart rate and stroke volume, whereas the arteriovenous difference in blood oxygen content is determined by the hemoglobin concentration, hemoglobin saturation with oxygen in both arterial and venous blood, and the extraction ratio. The extraction ratio is the proportion of oxygen that is removed from the blood during its passage through tissues. In animals with a normal hematocrit and cardiac output, oxygen delivery to tissues exceeds the oxygen requirements of the tissue by a large margin, with the result that the oxygen extraction ratio is small (<40%). However, as the oxygen-carrying capacity per unit of blood declines (usually expressed as mL of oxygen per 100 mL of blood) then either blood flow to the tissue or the extraction ratio must increase to maintain oxygen delivery.49-50 In reality, both of these compensatory mechanisms occur during the acute and chronic responses to anemia. Heart rate increases to increase cardiac output and therefore the delivery of oxygen to tissue, and blood flow is preferentially directed to those tissue beds that are most essential for life or are most sensitive to deprivation of oxygen (heart, brain, gut, kidney). Extraction ratio increases and is evident as a decrease in venous blood hemoglobin saturation. Hemoglobin in arterial blood is usually thoroughly saturated with oxygen and the limitation to oxygen delivery to tissue is the low hemoglobin concentration and consequent low arterial oxygen content. Assessment of arterial blood oxygen tension and content is discussed in Chapter 10.

Reductions in hemoglobin concentration are compensated for by increases in cardiac output and extraction ratio so that oxygen delivery to tissue is maintained in mild to moderate anemia.49 As the severity of anemia increases, these compensatory mechanisms are inadequate and oxygen delivery to tissues declines. At some point the delivery of oxygen fails to meet the oxygen needs of the tissue and organ function is impaired. It is important to realize that this is not an all-or-none phenomenon and that there is not a particular point at which decompensation occurs. In fact, with progressive anemia there are progressive increases in cardiac output and oxygen extraction ratio (evident as a progressive decline in venous hemoglobin saturation) until these compensatory mechanisms are maximal.49 Arterial pH and lactate concentration are maintained until the degree of anemia cannot be compensated for by increases in cardiac output and extraction ratio, at which point blood lactate concentration rises and blood pH and base excess decline. This is the degree of anemia at which oxygen use by tissue is entirely dependent on blood flow — decreases in blood flow decrease oxygen utilization and increases in blood flow increase oxygen utilization until the point where oxygen delivery exceeds oxygen consumption.

Compensation for slowly developing anemia is more complete than for rapidly evolving anemia such that animals with chronic anemia can tolerate a degree of anemia that would be intolerable for animals with acute anemia of a similar severity. Part of this chronic compensation includes changes in the affinity of hemoglobin for oxygen, which is due in part to increases in 2,3-diphosphoglycerate concentration in red cells.

- Radiation injury
- Poisoning by bracken, trichloroethylene-extracted soybean meal, arsenic, furazolidone and phenylbutazone, cause depression of bone marrow activity
- A sequel to inclusion body rhinitis infection in pigs
- Porcine dermatitis and nephropathy syndrome
- Intestinal parasitism, e.g. ostertagiasis, trichostrongyles in calves and sheep, have this effect.

</table>
When anemia is sufficiently severe that it reduces oxygen delivery to tissue to rates that are less than the oxygen needs of tissue, tissue hypoxia develops and the proportion of energy generated by anaerobic metabolism increases. **Anaerobic metabolism** cannot be sustained for more than a short period of time (minutes) before tissue function is impaired. Impaired organ function is evident as decreased myocardial contractility, decreased cerebral function, decreased gastrointestinal motility and abnormal renal function, to list just a few of many important abnormalities. The severity of these abnormalities depends on the metabolic activity of the tissue with more metabolically active tissues (e.g. the heart) being more sensitive to hypoxia. Death usually results from acute heart failure due to arrhythmia.

The effect of anemia is also dependent on the **metabolic state** of the animal. Exertion, even mild exertion such as grazing or following a herd or flock, can increase oxygen demands above that which can be sustained by the degree of anemia. Similarly, increases in body temperature, such as with fever, increase oxygen demand noticeably — an increase in body temperature of 1°C increases oxygen need by 12%.

Anemia induces increases in plasma erythropoietin concentration, which stimulates erythropoiesis in bone marrow and, in young animals or those with extreme anemia, in extramedullary sites. The increase in plasma erythropoietin concentration is prompt, occurring within hours of the development of anemia. The compensatory erythropoietic response is slower, with new red cells being detectable in 1–2 days in most species and bone marrow reticulocytosis detectable in less than 1 week.56,57

**Autoimmune hemolytic anemia**

The disease is believed to result from an aberrant production of antibodies targeted against surface antigens of the erythrocyte as a result of an alteration in the erythrocyte membrane from systemic bacterial, viral or neoplastic disease. An alternate hypothesis is the development of immunocompetent clones that direct antibody at the red cell membrane.17,24 Red cells are lost by intravascular hemolysis or removal by macrophages of the reticuloendothelial system and anemia occurs when the capacity of the bone marrow to compensate for increased red cell destruction is exceeded. Autoimmune hemolytic anemia is considered to be idiopathic if it cannot be associated with an underlying disease and is considered to be secondary if associated with another condition. Often this is neoplastic disease. The antibodies are of the IgG or IgM class, may be agglutinating or non-agglutinating and can also be temperature-dependent. The antiglobulin test has been used to confirm the diagnosis in cases of nonagglutinating autoimmune hemolytic anemia, but demonstration of immunoglobulin on the surface of red cells by immunofluorescent cell staining and flow cytometry is much more sensitive and specific.52,53

**Hemolysis**

Hemolysis results from rupture of red cell membranes as a consequence of injury to the membrane or osmotic lysis when serum tonicity is lower than normal. Hemolytic disease of any cause has the potential to overwhelm the normal clearance mechanisms for hemoglobin, with the result that hemoglobin concentrations in plasma are abnormally high. This can result in hemoglobinuric nephropathy (see Ch. 11).

**Methemoglobinemia and oxidative damage**

Methemoglobinemia results from oxidative damage of hemoglobin and occurs in disease such as red maple leaf toxicity in horses and nitrate poisoning in ruminants. Methemoglobinemia is reversible but important as an indicator of oxidative damage and because methemoglobin cannot transport oxygen. Oxidative damage to red cells results in denaturation of hemoglobin with subsequent formation of Heinz bodies. Red cells damaged in this way are sensitive to osmotic lysis and fragmentation. Intravascular hemolysis and removal of damaged red cells by the reticuloendothelial system contributes to anemia.

**CLINICAL FINDINGS**

The clinical signs and their severity depend on the degree of anemia. Mild anemia in animals that are not required to be physically active, such as veal calves or housed lambs, might be apparent only as failure to achieve optimal weight gain. More severe degrees of anemia, or mild anemia in animals required to be physically active, such as foals at pasture or race horses, can be evident as exercise intolerance, failure to perform athletically, or lethargy. Behavioral signs of anemia include prolonged recumbency, depressed mentation, reduced nursing, foraging or grazing and, in extreme anemia, belligerence.

Physical findings include pallor of the mucosa but appreciable degrees of anemia can occur without clinically visible change in mucosal or skin color. The mucous membranes, and skin in pale-skinned, sparsely haired animals such as pigs, can be almost white in animals with severe anemia. Hemolytic anemia causes jaundice in most cases.

A chart for examination of conjunctival color in sheep and goats has been validated as a means of assessing severity of anemia in these species. The chart (FAMACHA®) was developed to aid in parasite control programs.44 Conjunctival color is assessed on a scale of 1–5 in which 1 = red and 5 = white.54 The correlation between FAMACHA score and hematocrit was very good (R = 0.52 in sheep and −0.30 in goats). The sensitivity and specificity for detection of a hematocrit below 15% for FAMACHA scores of 4 and 5 were 83% and 89% for sheep, and 83% and 71% for goats. This methodology appears to be very useful for detection of anemia in small ruminants.

The heart rate is increased, the pulse has a large amplitude and the absolute intensity of the heart sounds is markedly increased in anemic animals. Terminal the moderate tachycardia of the compensatory phase is replaced by a severe tachycardia, a decrease in the intensity of the heart sounds and a weak pulse. A hemic murmur might be heard and is likely a result of the low viscosity of blood in anemic animals combined with increased ejection velocity of blood from the heart as a consequence of increased heart rate and cardiac output.

Dyspnea is not pronounced in anemia, the most severe degree of respiratory distress appearing as an increase in depth of respiration without much increase in rate. Labored breathing occurs only in the terminal stages and at those times the animals can be severely distressed.

Other signs of decompensated anemia include anxious expression, absent rumination, ileus, colic, anuria and cardiac arrhythmia. Animals can appear quiet and comfortable unless they are forced to move or an event occurs that increases oxygen consumption and causes decompen- sation. An example is an animal that has compensated for its severe anemia but then develops a fever. Fever can increase whole body oxygen requirement by 12% for each 1°C increase in temperature and this can cause a finely balanced animal to decompensate.

There can be signs of the inciting disease and these can include edema, jaundice, petechial and ecchymotic hemorrhages in the mucosa and hemoglobinuria. Adjunctive examination can include gastrointestinal, urinary or upper respiratory endoscopy; radiography of the chest or abdomen; and ultrasonographic examination of affected regions.

**CLINICAL PATHOLOGY**

The clinicopathological characteristics of the common forms of anemia are provided in Table 9.1.
Hematology

Anemia is definitively diagnosed by measurement of red cell indices and demonstration of low hematocrit, red cell count, and hemoglobin concentration. Examination of various red cell indices can yield important information about the cause of anemia and evidence of regeneration. In addition to providing the diagnosis, serial monitoring of the hemogram is useful in detecting evidence of a regenerative response. At a minimum, repeated measurement of hematocrit will reveal a gradual increase when there is a regenerative response. Hematocrit of horses with induced anemia increases by approximately 1% (0.01 L/L) every 3 days.55

Red cell morphological abnormalities include variations in size, shape, and content:

- **Red cell size**
  - Anisocytosis is the presence of red cells of abnormal size. Abnormal cells can be either macrocytes or microcytes. See Red cell distribution width
  - Macrocytosis (high mean corpuscular volume, MCV) usually indicates a regenerative response. Ruminants have a prominent macrocytic response to anemia. The increase in MCV in horses can be so slight as to be undetectable, especially in mild to moderate regenerative anemia
  - Microcytosis (low mean corpuscular volume) is found in classic deficiency anemias such as iron deficiency
  - Red cell distribution width is a measure of the variation in red cell size in the population of red cells in blood. It is calculated by dividing the standard deviation of red cell volumes by the mean red cell volume, and multiplying the product by 100. An increase in red cell distribution width indicates the presence of anisocytosis due to macrocytosis in regenerative anemia.51,55
  - Red cell distribution width is a measure of the variation in red cell size in the population of red cells in blood. It is calculated by dividing the standard deviation of red cell volumes by the mean red cell volume, and multiplying the product by 100. An increase in red cell distribution width indicates the presence of anisocytosis due to macrocytosis in regenerative anemia.51,55

- **Red cell shape**
  - Spherocytosis is found in diseases that affect the red cell membrane, such as immune-mediated anemia and red maple toxicosis
  - Schistocytes (small, irregularly shaped cells or red cell fragments) are found in diseases that cause intravascular physical injury to red blood cells, such as DIC or vasculitis with endothelial damage
  - Echinocytes are normal-sized red cells that have uniform membrane projects. They are of uncertain importance

- **Reticulocytes**
  - Reticulocytes are immature red cells released from the bone marrow. Reticulocytes contain remnants of nucleic acid and this can be detected by use of appropriate stains. Until recently, reticulocytosis in response to anemia was documented in ruminants52 and pigs, but not in horses. This was because equine reticulocytes do not stain with Romanovsky and other stains used for routine examination of smears of peripheral blood.

- **Eccentrocytes** are cells in which hemoglobin has been damaged and accumulated eccentrically in the cell, causing variation in color density of the cell. Usually associated with diseases causing oxidative damage

- **Reticulocyte content**
  - Polychromasia, the presence of erythrocytes of varying staining intensity, is usually due to the presence of reticulocytes
  - Hypochromia can be evident as reduced staining intensity and is due to a reduction in red cell hemoglobin concentration
  - The amount of hemoglobin in red cells can vary. **Mean corpuscular hemoglobin** (MCH) content increases in the presence of reticulocytes. False increases in MCH occur when there is free hemoglobin in plasma, either from in-vivo or ex-vivo hemolysis.

**Mean corpuscular hemoglobin concentration** (MCHC) is reduced in the presence of reticulocytosis and hemolysis falsely increases MCHC

- Nucleated red cells appear in the peripheral blood only in ruminants among farm animals and only in response to severe anemia
- Howell-Jolly bodies are nuclear remnants that are common in the regenerative response in ruminants but less so in horses
- Heinz bodies are round protrusions from the cell membrane or intracellular inclusions. The bodies are denatured hemoglobin and are found in diseases in which there is oxidative damage to red cells. Affected cells are fragile and susceptible to intravascular lysis or increased rate of removal by cells of the reticuloendothelial system

- Parasites such as **Babesia spp., Theileria spp., and Mycoplasma spp.** (formerly *Erythrozoon spp.*) can be detected in parasitemic animals

- Reticulocytes are immature red cells released from the bone marrow. Reticulocytes contain remnants of nucleic acid and this can be detected by use of appropriate stains. Until recently, reticulocytosis in response to anemia was documented in ruminants and pigs, but not in horses. This was because equine reticulocytes do not stain with Romanovsky and other stains used for routine examination of smears of peripheral blood.

- However, use of oxazin, a stain that combines with nucleic acid, and fluorescent detection of labeled cells has revealed the presence of reticulocytes in peripheral blood of horses.51 Horses develop a reticulocytosis in response to anemia, as do other species

- Reticulocyte volume and reticulocyte hemoglobin content increase in regenerative anemia in horses51 but has not been evaluated in other large animals.

**Agglutination** of red cells is apparent as irregularly shaped agglomerations of red cells. The clumps of red cells do not dissociate when blood is diluted 1:4 with 0.9% saline, as happens with rouleaux. Rouleaux are normal findings in blood of horses and are apparent as rows of erythrocytes.

**Coombs testing** or use of direct immunofluorescent flow cytometry can provide evidence of immune-mediated hemolytic anemia.52,53

Other hematologic changes in severe anemia include leukocytosis and thrombocytosis.

**Bone marrow**

Examination of bone marrow is useful for demonstrating a regenerative response, especially in horses in which a regenerative response can be difficult to detect in peripheral blood, and for determining the cause of nonregenerative anemia.

**Collection of bone marrow**

Samples of bone marrow can be obtained by aspiration, with samples submitted for cytological examination, or biopsy, with core samples submitted for histological examination. Bone marrow aspirates are useful in that they provide samples in which the relative proportions of myeloid and erythroid cell lines can be determined. However, samples obtained by aspiration do not allow examination of the overall cellularity of the marrow or its architecture.

Samples of bone marrow can be obtained from the sternbrae, proximal aspects of the ribs or tuber coxae. The preferred site in adult animals, and in calves, is the cranial sternurn. The procedure is performed on standing adult animals or laterally recumbent calves. Animals should be adequately restrained, which could include administration of sedatives and analgesics. A site on the ventral midline over the second or third sternurn is clipped and aseptically prepared. Local analgesia is induced by injection of lidocaine or similar local anesthetic (5–10 mL). The local anesthetic is injected subcutaneously and to the
surface of the sternebra. A small skin incision is made and the aspiration needle or biopsy instrument is introduced. Bone marrow aspirates can be collected using a 13–15-gauge, 5–7 cm needle and styllet. Bone marrow core biopsies are performed using an 8-, 11- or 13-gauge 100–150 mm bone marrow biopsy needle (Trap-System®).

Bone marrow aspirates are collected from adult horses by advancing the needle approximately 2–3 cm into the sternebra. The styllet is then removed, a 5–10 mL syringe is attached and bone marrow is aspirated. The samples should be placed on a clean glass slide and air-dried, or put in a Petri dish containing 0.5–1.0 mL of 2% EDTA.

Core samples of bone marrow are obtained by inserting the biopsy needle 2 cm into the cortex of the sternebra. The styllet is then removed and the needle is advanced with a rotating motion. This can require considerable effort in adult animals. The needle is advanced approximately 2–3 cm and then rapidly withdrawn. A sample of bone marrow will be evident as pink to red bone. The sample should be rolled on a clean, dry glass slide (for cytological examination) and then placed in 10% neutral buffered formalin for histological examination.

Interpretation of bone marrow

Bone marrow is examined for overall architecture, cellularity, the ratio of myeloid to erythroid cells (M:E ratio) and the presence of inflammation, necrosis or abnormal cells. A subjective assessment of iron stores can be made by staining sections of marrow with Prussian blue stain.

A regenerative response is evident as a low M:E ratio due to erythrocyte hyperplasia, and the presence of erythroid series cells in all stages of maturity. There are increased counts of reticulocytes in bone marrow and the number of nucleated cells relative to the hematocrit increases. The MCV and reticulocyte hemoglobin content are high in regenerative bone marrow. These responses are evident as soon as 3 days after acute anemia and peak at approximately 9 days.

Abnormal white cells, such as seen in myelophthitic disease caused by myeloma or lymphosarcoma, cause displacement of erythroid series cells and a high M:E ratio. Similarly, a high M:E ratio is obtained when there is primary red cell aplasia. A normal M:E ratio is obtained when there is aplasia of both myeloid and erythroid series of cells, highlighting the need to evaluate overall cellularity of the marrow. Normal marrow is approximately 50% fat and 50% combined myeloid and erythroid series cells.

**Blood gas analysis, oximetry and lactate**

**Arterial blood gas analysis**

Arterial blood oxygen tension (mmHg, kPa) in animals with anemia is almost always within the reference range for healthy animals unless there is coexisting lung disease. Anemia does not interfere with diffusion of oxygen from the alveolus into capillary blood. However, the arterial oxygen content (mL O₂ per 100 mL blood) is reduced because of the reduced arterial blood hemoglobin concentration (see Ch. 10). Arterial carbon dioxide tension is often reduced in severe anemia as a result of alveolar hypoventilation that is a response to arterial hypoxemia. Arterial pH and base excess decline as the severity of anemia increases and compensatory mechanisms are no longer able to ensure delivery of sufficient oxygen to tissue the, indicative of metabolic acidosis resulting from tissue anaerobiosis.

**Venous blood gas analysis**

The ideal sample is mixed venous blood collected from the pulmonary artery or right atrium. However, these sites are only infrequently available for collection so samples should be collected from a major vein (jugular vein, cranial vena cava). Samples collected from small leg veins are less than ideal. Measurement of venous blood gas tensions, pH, base excess, hemoglobin saturation and oxygen content are useful in evaluating the physiological effect of anemia. As discussed under pathophysiology, reductions in oxygen content of arterial blood cause an increase in oxygen extraction ratio in an attempt to maintain oxygen delivery to tissue. The increased extraction ratio is evident as a reduction in venous oxygen tension, hemoglobin saturation and oxygen content.

When oxygen delivery to tissue is less than that needed to maintain aerobic metabolism, venous pH, bicarbonate concentration and base excess decline.

**Methemoglobinemia**

Measurement of methemoglobin concentration is useful in documenting the presence of pigmenturia, red cells and myoglobinemia in anemic animals

**Other evaluations**

**Feces** should be examined for the presence of parasites (ova, larvae or adult parasites), frank blood (hematochezia or melena) and occult blood. Detection of occult blood can be difficult and samples should be collected on multiple occasions. Samples should not be collected soon after rectal examination, as false-positive results can be found because of trauma to the rectal mucosa.

**Urine** should be evaluated for the presence of pigmenturia, red cells and casts. Pigmenturia should be differentiated into hemoglobinuria or myoglobinuria. Microscopic examination will reveal red cells, or ghost red cells, in animals with hematuria. Casts and isosthenuria can be present in urine of animals with hemoglobinuric nephrosis.

**Serum erythropoietin concentration** should be evaluated in animals with nonregenerative anemia. It is not a readily available assay. Concentrations of erythropoietin in adult horses are usually less than 37 mU/mL, but values are probably dependent on the assay used.
Tests for **specific diseases** should be performed as appropriate:
- Measurement of bleeding time, PT, APTT and platelet count should be considered in animals with evidence of excessive unexplained hemorrhage
- Examination for blood parasites
- Serological testing for infectious causes of anemia
- Toxicological testing.

**NECROPSY FINDINGS**
Findings indicative of anemia include pallor of tissues, thin, watery blood and contraction of the spleen. Icterus may be evident where there has been severe hemolytic anemia and petechial and ecchymotic hemorrhages with thrombocytopenia. Necropsy findings specific to individual diseases are given under those disease headings.

**TREATMENT**
The principles of treatment of anemia are ensuring adequate oxygen transport to tissues, prevention of the deleterious effects of anemia or hemolysis, and treatment of the inciting disease. The individual inciting diseases are discussed elsewhere in this text.

**Correction of anemia**
The discussion here deals with nonvolemic anemia. Acute anemia with hypovolemia (hemorrhagic shock) is dealt with in Chapter 2.

Transfusion
The oxygen-carrying capacity of blood should be restored in the short term to at least the level at which oxygen use by tissue is not flow-dependent, and to normal levels in the longer term. Short-term restoration of the oxygen-carrying capacity of blood is achieved by transfusion of whole blood or packed red cells, or administration of a commercial stromal free hemoglobin solution.

The decision to transfuse an anemic animal should not be undertaken lightly for a number of reasons. Transfusion of blood or packed red cells is not without risk to the recipient, there is usually considerable cost in identifying a suitable donor and collecting blood, and the process can be time-consuming. An important concern in performing a blood transfusion is the risk to the recipient. Acute reactions, include anaphylaxis and acute host versus graft reaction (hemolysis of transfused red cells), and graft versus host disease (hemolysis of recipient red cells). Development of alloantibodies in the recipient with consequent problems with repeat transfusion or development of neonatal alloimmune hemolytic anemia in progeny of female recipients is a concern. The incidence of these adverse events has not been recorded for large animals but can be minimized by crossmatching donor and recipient.

**Crossmatching** and the mechanics of blood transfusion are discussed in Chapter 2 and elsewhere.

Briefly, both major (donor red cells and recipient plasma) and minor (donor plasma and recipient red cells) crossmatching should be performed. Ideally, blood typing and examination of plasma for alloantibodies of both donor and recipient would be performed before transfusion, but these are rarely available in an appropriate time frame.

**Indications** for transfusion are not straightforward. Because of the risk to the recipient and cost, blood transfusion should be performed only when indicated. Conversely, the severe adverse effects of anemia mean that animals should not be denied a transfusion if it is needed. There is no one variable for which a single value is a 'transfusion trigger', and the decision to provide a transfusion should not be based on hematocrit, hemoglobin concentration or red cell count alone. Rather, the decision to provide a transfusion should be based on a holistic evaluation of the animal, including the history, physical abnormalities and clinico-pathological data. This information should be considered in total before a decision is made to provide a transfusion. Considerations regarding transfusion include:
- **History** – animals with acutely developing anemia are more likely to require transfusion at a given hematocrit than are animals with slowly developing anemia. Similarly, young animals with higher intrinsic metabolic rates might require transfusion at hematocrit values that would be tolerated by adults
- **Physical findings** – these are some of the most important indicators of the need for transfusion and include:
  - Changes in demeanor and activity including lethargy, belligerence, anxiousness, depressed mentation, anorexia, intolerance of minimal exercise (nursing, walking), prolonged or excessive recumbency
  - Tachycardia. There is no one value that is critical, but a heart rate that is 30–50% above the upper limit of normal is probably important. Progressive increases in heart rate are indicative of the need for transfusion
  - Sweating, cold extremities, and other signs of sympathetic activation
  - Absent rumination, ileus, gastrointestinal distension, colic
  - Arrhythmias, including ventricular premature beats
  - Anuria
  - Clinical pathology
- **Decline in hematocrit with exacerbation of abnormalities on physical examination.** Transfusion should be considered in any animal with a hematocrit below 20% (0.20 L/L). Most animals do not need a transfusion at this level, but the proportion that requires a transfusion increases at lower hematocrits. Some horses with chronic anemia and a hematocrit of 10% (0.10 L/L) do not need a transfusion, whereas others with acute anemia of 15% (0.15 L/L) need a transfusion urgently
- Venous blood hypoxemia and declines in hemoglobin saturation. There is no one value that is critical as there are progressive and gradual declines in these variables as oxygen content of arterial blood declines. Venous blood oxygen tension of less than 25 mmHg is clinically significant and values below 20 mmHg probably represent the need for transfusion
- Venous pH and base excess. Development of acidosis (low base excess) and acidemia (low pH) are indications of tissue anaerobiosis and the need for transfusion. Unlike venous blood oxygen tension and saturation, these values are normal until decompensation occurs
- Lactate concentration (arterial or venous). Blood lactate concentrations rise rapidly when decompensation occurs. Blood lactate concentrations above 2 and below 4 mmol/L should be cause for concern and prompt closer monitoring, whereas values above 4 mmol/L probably indicate a need for transfusion
- Evidence of organ damage, including increases in serum creatinine or bile acid concentration indicators of hepatocellular damage, and troponin.

Transfusion to correct anemia in normovolemic animals should be done cautiously to minimize the risk of excessive expansion of the intravascular volume. Ideally, packed red cells can be administered to reduced the extent of blood volume expansion. However, preparation of packed red cells can be difficult and time-consuming. An alternative with horses is simply to allow the collected blood to sit undisturbed for 1–2 hours.
during which time the cells will settle to the bottom. The red cells can then be siphoned off and administered to the recipient.

Details of donor selection, blood collection and blood administration are provided in Chapter 2.

An alternative to transfusion of whole blood or packed red cells is the administration of a commercial preparation of stromal free hemoglobin. This product is effective in increasing oxygen-carrying capacity of blood in anemic horses and has been used for support of a foal with anemia until a blood transfusion was available.\(^3,9,10\) The compound is stable at room temperature and can therefore be stored for long periods of time and be readily available for use. However, it is expensive and its effect is short-lived (<48 h and probably less). The recommended dose is 15 mL/kg BW intravenously, but lower doses have been used. The compound increases oncotonic pressure of plasma and causes expansion of the plasma volume.

The efficacy of transfusion can be assessed by examination of the animal and measurement of venous blood oxygen tension and saturation, and blood lactate concentration. Venous blood oxygen tension and saturation improve promptly with transfusion of an adequate red cell mass.

Hematinsics

Hematinic preparations are used in less severe cases and in animals with anemia due to iron deficiency or severe external blood loss (see Table of Drug Doses in Appendix). Iron is administered to prevent iron deficiency in young animals denied access to pasture or soil. The use of recombinant human erythropoietin in horses has a risk of inducing anemia.\(^4,5\) Given that there are no known causes of low erythropoietin concentrations causing anemia in horses, with the exception of those horses with anemia subsequent to rhEPO administration, the use of this compound in horses is specifically contraindicated.

Supportive care

The oxygen requirements of anemic animals should be minimized. This can be achieved by housing them individually in quiet stalls the temperature of which is maintained in the animal's thermoneutral zone, minimizing the need for exercise (such as grazing or following the mare to nurse), and maintaining a normal body temperature.

Animals with hemolytic anemia and hemoglobinuria should be administered polyionic isotonic fluids intravenously to reduce the risk of hemoglobinuric nephrosis.

Treatment of autoimmune hemolytic anemia

Some animals with autoimmune hemolytic anemia respond well to administration of corticosteroids.\(^2,24\) Compounds used include prednisolone and dexamethasone. Horses with refractory aplastic anemia or hemolytic anemia have been administered cyclophosphamide (2 mg/kg intravenously every 14-21 d) in addition to glucocorticoids.

**REFERENCES**

**ERYTHROCYTOSIS**

Erythrocytosis is an increase in erythrocyte count, hemoglobin concentration and hematocrit in blood. Polycythemia vera, a disease of humans and rarely small animals, and scarcely reported in cattle,\(^1\) is due to an increase in concentration of all blood cellular elements (erythrocytes, granulocytes and platelets). Erythrocytosis, which is due solely to an increase in red cell count, is either relative or absolute.

**Relative erythrocytosis** occurs when the total body red cell mass (i.e. the total amount of red cells in the body) is not elevated above normal, but the red cell count in peripheral blood is higher than expected. This is the most common form of erythrocytosis. Relative erythrocytosis occurs both as an abnormality and as a physiological response to physical or psychological stress in animals with a capacious and capricious spleen. Abnormal relative erythrocytosis results from hemoconcentration and is evident as an increase in concentration of red cells and serum total protein. The cause is a reduction in plasma volume, which is usually associated with dehydration due either to lack of water intake or to excessive losses (diarrhea, vomiition). The diagnosis is usually obvious, based on the presence of hemoconcentration and other signs of the underlying disease. Physiological relative erythrocytosis occurs most noticeably in horse as a result of either excitement or exercise. The blood in the spleen of horses has a hematocrit much higher than that of blood (70-80%) and when relaxed the spleen contains many liters of blood. Excitement or exercise cause splenic contraction through an alpha-1-mediated event and ejection of
the red-cell-rich blood into the peripheral circulation, with subsequent marked increases in hematocrit.2,3 The spleen of an adult horse can eject 5–10 L of blood into the circulation, which, together with a decline in plasma volume during exercise, increases hematocrit to 55–60% (0.55–0.60 L/L).2

Absolute erythrocytosis occurs because of an increase in the number of red blood cells in the body. It is classified as primary or secondary, and within secondary erythrocytosis there is a further classification of appropriate or inappropriate. Primary erythrocytosis is attributable to proliferation of erythroid progenitors with maturation of the red cell series in the absence of arterial hypoxemia or increases in plasma erythropoietin concentration. It is a myeloproliferative disorder. Disorders resembling primary erythrocytosis are described in horses.4,5 These horses had marked increases in red cell count without evidence of diseases causing arterial hypoxemia or tissue hypoxia and without increases in serum erythropoietin concentration. A familial erythrocytosis is documented in cattle, but the disease resolved as animals matured, which is not consistent with primary erythrocytosis due to a myeloproliferative disorder.6

Secondary erythrocytosis is classified as either appropriate or inappropriate. Appropriate secondary erythrocytosis occurs as a consequence of diseases that cause tissue hypoxia with subsequent increases in plasma erythropoietin concentration. Tissue hypoxia is often inferred from the low arterial blood oxygen tension or content in these diseases. Tissue hypoxia can occur in the face of normal arterial blood oxygen tension when there is an abnormality in hemoglobin (such as chronic hemoglobinemia or carboxyhemoglobinemia), although this has not been reported as a cause of erythrocytosis in large animals. Diseases causing appropriate secondary erythrocytosis include chronic lung or respiratory disease, and congenital cardiac anomalies in which there is right-to-left shunting (such as Eisenmenger’s complex in cattle). Physiological appropriate secondary erythrocytosis occurs in animals living at high altitude.

Inappropriate secondary erythrocytosis occurs in animals that do not have arterial hypoxemia or diseases causing tissue hypoxia. Plasma erythropoietin concentrations are elevated despite there being normal arterial oxygen tension and content, hence the term ‘inappropriate’. The disease is usually associated with hepatic or renal neoplasia. The disease in horses is described in foals or young animals with hepatoblastoma.4,8 and adults with hepatic carcinoma.9,10 Erythrocytosis is recorded in a mare with a lymphoma that expressed the gene for equine erythropoietin, suggesting that anomalous production was the cause of the secondary inappropriate erythrocytosis.11 Erythrocytosis also occurs in horses with liver disease.12 The cause is not known, but could involve increased production of erythropoietin or decreased clearance because of reduced hepatic function. Inappropriate secondary erythrocytosis in ruminants or pigs is not reported, but probably occurs.

The clinical signs of secondary erythrocytosis are those of the underlying disease (dyspnea, congestive heart failure, cyanosis). In addition, the erythrocytosis can be evident as dark red or slightly purplish mucous membranes, lethargy and an increased propensity for thrombosis. These signs occur because of the increase in blood viscosity that results from marked increases in red cell concentration. Treatment is directed toward the inciting disease. For animals with primary erythrocytosis, repeated phlebotomy and restriction of iron intake has been used to reduce the red cell count.7

A syndrome is described in Standardbred trotters in Sweden that have normal red cell count at rest but counts during maximal exercise that are higher than expected.13 The syndrome is referred to as ‘red cell hypervolemia’ and is associated with poor race performance. Diagnosis is based on a history of poor performance and hematocrit or red cell counts during maximal exercise or after administration of epinephrine that are higher than expected. Treatment is prolonged rest, although some horses have had phlebotomy and therapeutic bleeding.

Hemoglobinopathies are not well documented in large animals, with the exception of changes caused by ingestion of oxidants (nitrate, onions, kale, red maple leaves) that cause methemoglobinemia, or the recognition that inhalation of carbon monoxide causes carboxyhemoglobinemia. Both carboxyhemoglobinemia and methemoglobinemia decrease oxygen carriage by hemoglobin.

Reported abnormalities in red cell metabolism include:
- Diminished glucose-6-phosphate activity of red cells caused hemolytic anemia in an American Saddlebred colt
- Flavine adenine dinucleotide deficiency is reported in a Spanish mustang with mild and variable anemia
- Glutathione reductase deficiency causing hemolytic anemia in a horse

Other abnormalities of glutathione metabolism, with minimal clinical expression, occur in sheep and horses.6

Disorders of white cells

LEUKOPENIA

Leukopenia does not occur as a specific disease entity but is a common manifestation of a number of diseases. Neutropenia, often accompanied by lymphopenia, occurs with a number of acute viral diseases such as hog cholera and equine viral arteritis. It has also been observed in leptospirosis in cattle, although bacterial infections are usually accompanied by a leukocytosis. Acute local inflammation may cause a transient fall in the leucocyte count because of withdrawal of the circulating cells to the septic focus. Neutropenia occurs as part of the response to toxemia, and in particular endotoxemia, because of enhanced migration of neutrophils from blood into tissues. The emigration of neutrophils occurs at a rate faster than their entry into the peripheral blood from bone marrow. Lymphopenia occurs as part of a stress response, and as a result of administration of glucocorticoids.

Leukopenia also occurs as part of a parapytosis in which all cellular elements of the blood are depressed. Agents that

ABNORMAL RED CELL FUNCTION

The primary function of red blood cells is to transport oxygen. Abnormal red cell function that results in anemia is dealt with under that heading. Abnormalities of red cell function can include abnormalities in red cell metabolism or the structure or function of hemoglobin.

REFERENCES
depress the activity of the bone marrow, spleen and lymph nodes and result in pancytopenia occur in poisonings caused by trichloroethylene-extracted soybean meal, toluene, fungal toxins, e.g. fusario­
toxosis, notably that of Stachybotrys alternans, and bracken fern. Pancytopenia occurs also in radiation disease and in calves ascribed to furazolidone poisoning. The disease is discussed under the title of
granulocytic calf disease. Chronic arsenical poisoning and poisoning by sulfonamides, chlorpromazine and chloramphenicol cause similar blood dyscrasias in humans but do not appear to have this effect in animals. Leukopenia in pigs can occur as a result of iron deficienc.'

Administration of glucocorticoids causes a lymphopenia and eosinopenia in most species. Lymphopenia is present in animals with immune deficienc' as well as combined immunodeficiency in Arabian foals and Fell pony foals with immunodeficiency.

The importance of leukopenia is that it may reduce the resistance of the animal to bacterial infection. Treatment of the condition should focus on the underlying disease, but broad-spectrum antibiotics are often administered because of the presumed greater risk of bacterial infec­
tion in leukopenic animals.

REFERENCE

LEUKOCYTOSIS

Leukocytosis, a white blood cell count in peripheral blood greater than expected in healthy animals, can be an appropriate physiological response to an infectious or inflammatory process, a result of white cell dysfunction or a result of leukopo­
erative disease. In this last instance, a particular situation is that in which there is neoplasia of the immune cells with subsequent production of growth factors or interleukins that stimulate inappropriate proliferation of other cells types that are detectable in the peripheral blood. An example is horses with intes­
tinal lymphosarcoma that have peripheral eosinophilia. The leukoproliferative diseases are dealt with under that heading.

Leukocytosis can be a result of an increase in concentration of all white blood cells or a result of increases in count of a particular subset. The changes include lymphocytosis, neutrophilia, eosinophilia, monocytosis and basophilia. Thrombocytosis is dealt with under that heading.

Lymphocytosis not related to infection by bovine leukemia virus is unusual. Chronic viral or bacterial infections can result in mild increases in lymphocyte count in blood but these changes have little diagnostic significance. The ratio of T lymphocytes to B lymphocytes changes in some disease processes, but these sub­
sets are seldom differentiated in routine clinical practice.

Neutrophilia is almost always a response to an inflammatory process, with the exception of the neutrophilia associated with stress ('stress' leukogram). Subacute to chronic bacterial disease or inflammation causes marked increases in neutrophil count in peripheral blood. The neutrophilia is variable and can reduce even in the presence of continuing disease, such as R. equi pneumonia. A mature neutrophilia is evident as a high neutrophil count in the absence of immature forms (band cells). A regenera­
tive neutrophilia is characterized by normal to elevated neutrophil counts and the presence of an excessive number of immature neutrophils (so-called 'left shift'). The presence of a left shift suggests either rebound neutrophilia subsequent to neutropenia, or ongoing severe inflam­
mation. Mature neutrophilia suggests inflammation of longer standing but is not definitive for this time frame. Mature neutrophilia can occur during the recovery stage from anemia, especially hemolytic anemia. Profound neutrophilia occurs in calves with bovine leukocyte adhesion deficiency and in some septi­
cemic foals.

Eosinophilia is usually associated with allergy or parasitism. Examples include milk allergy in cows and intestinal parasitism in horses. Eosinophilia can occur in horses with intestinal lympho­
sarcoma or multisystemic eosinophilic eptheliotropic disease.

Monocytosis and basophilia are unusual in large animals with the excep­
tion of that occurring as part of a rebound bone marrow response to profound neutropenia.

ABNORMAL WHITE CELL FUNCTION

Abnormalities of white cell function can be either congenital or acquired. Congenital defects include Chédiak–
Higashi syndrome and bovine leukocyte adhesion deficiency. Acquired defects include those associated with neoplasia of cells of the innate and adaptive immune systems, and dysfunction induced by disease, intoxication or deficiency (such as iron deficiency impairing neutrophil function). A wide variety of infectious diseases can impair function of a white blood cells, including phagocytosis of microorganisms by neutrophils or macro­
phages. Intoxicants such as some of the mycotoxins impair leukocyte function. Malnutrition, starvation and specific deficiencies (e.g. iron) impair leukocyte function.1

REFERENCE

LEUKOPROLFERATIVE DISEASE

The leukoproliferative diseases are neoplastic diseases of the myeloid (hemapoietic) or lymphoid tissues. The discussion here will be divided into those diseases associated with abnormal lymphoid cells (lymphoproliferative) and those associated with abnormal myeloid cells (myeloproliferative). The most common leukoproliferative diseases of large animals are lymphoma and lymphosarcoma.

MYELOPROLIFERATIVE DISEASES

Myeloproliferative disease is rare in large animals but granulocytic, eosinophilic, monocytic and myelomonocytic leukemias are reported:

- Acute (myelogenous) and chronic granulocytic leukemia are reported in horses1,2
- Acute granulocytic leukemia in a goat3
- Systemic mastocytosis in a goat4
- Acute myeloblastic leukemia in cattle and horses5
- Myelomonocytic leukemia in a calf6
- Malignant histiocytosis in cattle7 and horses8
- Eosinophilic myeloproliferative disease in a horse.9

Cases manifest with nonspecific clinical signs including weight loss, poor perfor­
mance, episodic ventral and lower limb edema, petechial hemorrhage, spleno­megaly, and some with lymph node enlargement or palpable masses in the abdomen in some. Thrombocytopenia and anemia are common because of myelophthisis. Abnormal cells are often apparent on examination of a smear of peripheral blood. Immunohistochemistry and immunostaining of cells for fluor­
escent cell sorting can identify the abnormal cells.

The diagnosis is often obtained at necropsy examination. Antemortem diag­
osis can be facilitated by examination of peripheral blood smears and bone marrow obtained by aspiration or biopsy.

There is no effective treatment, nor are there measures to prevent the disease.

REFERENCES

LYMPHOPROLIFERATIVE DISEASE

Lymphoproliferative disease occurs in all large animal species but is common only in cattle, where it manifests as lymphoma or lymphosarcoma (bovine viral leukosis). The other lymphoproliferative disease is plasma cell myeloma, which occurs in ruminants and horses. Lymphangiosarcoma is a rare tumor of lymphoid endothelium in horses and cattle.1,2

Plasmacytoma (multiple myeloma)

This is a tumor of plasma cells that sometimes results in production of monoclonal globulins. The disease occurs in cattle, sheep, and horses and is characterized by proliferation of lymphoid cells that produce an immunoglobulin or immunoglobulin fragment (often referred to as M-protein). The disease characteristically, but not always, involves the bone marrow, in which case it is referred to as multiple myeloma. The tumor cells may or may not secrete abnormal protein.

Clinical signs are often nonspecific and include weight loss, anorexia, limb edema and recurrent infections. There can be signs of excessive bleeding as a result of minor trauma such as needle sticks. The tumor can infiltrate many tissues, accounting for the protean nature of the clinical signs. Involvement of cranial nerves can result in dysphagia and infiltration of cervical vertebrae can result in pathological fracture and acute spinal cord compression. Involvement of the mediastinal lymph nodes can cause signs of an anterior thoracic mass. The clinical signs can be sufficiently vague that the disease is easily overlooked in its early stages. Radiography reveals the presence of osteolytic bone lesions in some animals.5

Anemia is common and thrombocytopenia occurs in about 20% of affected horses. Plasma cells can occasionally be seen in smears of peripheral blood. Hypoalbuminemia and hyperglobulinemia are common findings. Serum protein electrophoresis is useful in demonstrating the presence of a monoclonal proteinopathy in the alpha-2, beta, or gamma regions. Bence-Jones proteinuria occurs in approximately 20% of horses with myeloma.3 Serum concentrations of specific immunoglobulins are often increased — there are two reports of horses with myeloma and elevated concentrations of IgA.6,7 Hypercalcemia occurs in some affected horses5-7 and can be a result of increased concentrations of parathyroid-hormone-related protein.6 Examination of bone marrow obtained by aspiration or biopsy can reveal the presence of an excess number of plasma cells (> 10%).

There is no effective treatment. Most animals present with advanced disease and die within days to weeks, but animals detected earlier in the disease process can live for more than 6 months.6,7

Lymphoma and lymphosarcoma

Bovine leukosis virus causes lymphoma in cattle and sheep, but with these exceptions the etiology of lymphoma in large animal species is unknown.

Ruminants and pigs

Lymphosarcoma occurs as four distinct clinical entities in cattle:

- Juvenile multicentric lymphosarcoma occurs at birth or in early life. It is multiclonal and characteristically involves the bone marrow and most lymph nodes.
- Thymic lymphosarcoma develops in cattle from 3 months to 2 years of age and involves the thymus, occasionally spreading to other lymph nodes and rarely infiltrates other organs.
- Cutaneous lymphosarcoma occurs primarily in cattle at 1-3 years of age.
- Adult multicentric lymphosarcoma, bovine viral leukemia.

Lymphosarcoma in cattle is discussed in detail under the headings of bovine viral leukosis and sporadic bovine leukosis.

- Lymphoma associated with bovine leukemia virus occurs in sheep.10 The sporadic form of the disease can have a variety of presentations, including involvement of the brain, skin and joints in addition to the expected localization in lymphoid tissue.11-13
- Goats develop sporadic lymphoma including a multicentric form14-16
- Pigs develop lymphosarcoma sporadically, with most forms being of B cells, although disease due to T cells is described.17,18 There is also an inherited form of the disease.19,20

The clinical signs of lymphosarcoma are similar to those described for the disease associated with bovine leukemia virus in cattle. Lymphadenopathy and clinical abnormalities arising as a result of lympho-adenopathy (dysphagia, bloating, respiratory distress) are common presentations. Radiography or ultrasonography are useful diagnostic aids.13 Biopsy of lymph nodes can yield a diagnosis. Necropsy examination reveals lymphadenopathy and infiltration by neoplastic lymphocytes. There is no documented effective treatment. Administration of glucocorticoids might cause transient improvement because of lympholysis. Radiotherapy is feasible in small ruminants or pigs of sufficient monetary or emotional value, but has not been reported.

Horses

Etiology and epidemiology

There is no recognized etiology of lymphoma or lymphosarcoma in horses. The disorder is more accurately described as neoplasia of one of many lymphoid cell lines, and with increasing sophistication of immunohistochemical staining it is possible to differentiate lymphoma by the particular cell line that is affected. Both immunohistochemistry of fixed tissue sections and fluorescent cell sorting of cells in body fluids have been used to determine the abnormal cell type.21,22 An additional advantage of advanced testing is that tumors of uncertain origin (lymphoid, myeloid) can sometimes be characterized.22

The tumors in horses are most commonly of T-cell or B-cell lines. Equine B-cell lymphoma accounts for approximately 70% of equine lymphomas,21 B-cell lymphomas that do not contain large numbers of T cells (which are not neoplastic) account for 40% of equine lymphoma and are characteristically tumors of the spleen and thoracic and mediastinal lymph nodes. B-cell tumors that contain large numbers of T cells (T-cell-rich B-cell lymphoma) account for approximately one third of equine lymphoma. These latter are typically tumors of the skin and subcutis.21 T-cell lymphomas account for approximately 20% of equine lymphomas and typically cause disease involving mediastinal lymph nodes. Approximately 50% of equine lymphomas have cells that express progesterone receptors, but none express the estrogen receptor.23

The disease occurs in all ages of horse but there is no information on age-specific incidence. One study has reported cases in horses ranging from 4 months to 22 years of age24 and the mean age of cases in this, and other case reviews, suggests that there is some increase in risk with increasing age. Limited slaughter surveys show a prevalence that varies from 0.7 to 3.2 cases per 100 000 animals.25

Clinical signs

The clinical manifestation of lymphosarcoma in horses is probably best described by the statement that the disease can manifest in a protean manner. Lymphosarcoma can exert an influence on the function of any organ system and is determined by where it occurs in the body. Most cases, certainly over 50% of cases, are multicentric although they may present with signs that are

References

organ-specific and the multicentricity may not be recognized until further, more complete, clinical or postmortem examination. External lymphadenopathy is usually a reflection of multicentric disease. Common presenting histories for other cases include chronic wasting and chronic diarrhea, upper respiratory distress with stertorous breathing or inspiratory dyspnea, lower respiratory abnormality, subcutaneous edema, anemia and fever of unknown origin.

Lymphosarcoma is the single most common cause of neoplasia in the thorax of the horse. A common syndrome is that of weight loss, ventral edema of the neck and thorax, sometimes accompanied by pleural or peritoneal effusion, anemia, dyspnea, cough and abdominal masses palpable per rectum. In cases where the lesions are predominantly in the thorax the syndrome is that produced by a space-occupying lesion, manifested by pectoral edema, jugular vein engorgement but an absence of the jugular pulse and dyspnea. The heart may be displaced and there may be cardiac murmurs. If there is compression of the esophagus, dysphagia is present.

Another relatively common syndrome is chronic weight loss, with or without diarrhea, associated with infiltration of the intestine. A case review of chronic diarrhea in horses found alimentary lymphosarcoma to be the cause in five of 51 cases. Oral glucose tolerance tests are adversely affected by the intestinal infiltration of lymphosarcoma but an abnormal test is not pathognomonic for this disease. Lymphosarcoma is also a cause of recurrent colic in horses.

Cutaneous lymphosarcoma is a common disease in horses and might be the most common form of lymphoma in horses. The tumors can be solitary or multiple and are usually discrete, firm, nonpainful swellings. The swellings are often haired, but in the more severe disease there is loss of hair. The lesions tend to be on the head, neck and dorsal trunk, but can be anywhere on the body. The tumors sometimes metastasize but horses affected with a mild or waxing and waning disease can live for years. The tumor is usually a T-cell-rich B-cell lymphoma. Diagnosis is by excisional biopsy. Another variation is mycosis fungoides, a T-cell lymphoma of the skin that appears to have a more aggressive course. Pruritus with alopecia can occur as part of a paraneoplastic syndrome in horses with diffuse lymphoma.

Lymphosarcoma is the final diagnosis in a significant proportion of horses with fever of unknown origin and also should be considered in the differential diagnosis of horses with signs of ataxia or other signs of neurological disease. The organ systems affected by lymphosarcoma in the horse are not restricted to those mentioned above and individual horses may show involvement of virtually any body system.

Ultrasound can aid in the location of tumor masses or accumulation of pleural or peritoneal fluid, and in aspiration of material from these sites. Radiography is useful for detecting mediastinal disease. Rhinolaryngoscopy permits detection and assessment of disease of the pharynx.

Clinical pathology
A specific diagnosis can be obtained by cytology and needle aspirates or biopsy with cytological examination of affected lymph nodes is diagnostic. Samples can be obtained from enlarged lymph nodes or from bone marrow. Cytological examination of fluid obtained by thoracocentesis or abdominocentesis where there is thoracic or abdominal involvement is also frequently diagnostic.

Anemia is a consistent finding in horses with advanced lymphosarcoma. The anemia can be due to tumor cells occupying bone marrow, but this is not a usual manifestation of the disease. More commonly, anemia is probably due to increased destruction of red cells or anemia of chronic disease. Only a small proportion of horses with lymphadenopathy due to lymphosarcoma have concurrent leukemic blood changes. Sézary-like cells have been detected in the blood of a horse with B-cell lymphoma. Thrombocytopenia occurs in approximately 30% of cases.

Immunophenotyping cells obtained at necropsy examination, by biopsy of affected organs or lymph nodes, or from peripheral blood can aid in determining the cell type involved. Hypergammaglobulinemia and hypalbuminemia occur in some horses. Hypergammaglobulinemia in horses with lymphosarcoma is almost always due to a polyclonal globulinopathy — in contrast to horses with plasma cell myeloma — and is probably attributable to the inflammatory response to the tumor. Plasma fibrinogen concentrations can be elevated in horses with lymphosarcoma for the same reason.

Low serum immunoglobulin concentrations have been reported in horses with lymphosarcoma but this finding is not specific for lymphosarcoma. Detection of low serum IgM concentration has poor sensitivity and specificity for diagnosis of lymphosarcoma. The sensitivity and specificity of serum IgM below 60 mg/dL for diagnosis of lymphosarcoma in horses are 50% and 35%, respectively. This is not a good screening or diagnostic test for lymphosarcoma in horses.

Abnormalities in serum calcium concentration are uncommon and variable, with both hypocalcemia and hypercalcemia being reported. Hypercalcemia can be associated with elevated serum concentrations of parathyroid hormone related peptide.

Treatment
Treatment of lymphoma in horses is scarcely reported. Immunotherapy with cyclophosphamide and vaccinia-virus-infected autologous tumor cells resulted in some remission of disease in a stallion with cutaneous lymphosarcoma and the animal remained clinically stable for 19 months without tumor progression. Removal of an ovarian granulosa theca cell tumor in a mare with waxing and waning cutaneous lymphosarcoma was associated with regression of the tumor.

Radiotherapy of localized disease of the head and pharynx might be effective in treatment of the lymphoma in horses, as lymphoma in other species is radiosensitive. Surgical removal of isolated masses in the skin is appropriate in some cases of cutaneous lymphosarcoma.

Administration of oncolytic agents has resulted in remission of disease in some horses. Drugs used include prednisolone, vincristine, cyclophosphamide and cytarabine. The glucocorticoids cause lysis of abnormal lymphocytes and can result in some improvement in clinical signs. A protocol that has met with some success involves administration of cyclophosphamide (2 mg/kg, intravenously) once weekly for 4–6 weeks, and then once every 2–3 weeks, combined with oral administration of prednisolone (0.5–1.5 mg/kg every 24–48 h). Another protocol involves administration of vincristine (0.008 mg/kg intravenously) and cyclophosphamide (2 mg/kg intravenously) once every 2 weeks for four to six treatments, combined with daily administration of prednisolone. The aim of all these treatments is to induce remission or to reduce clinical signs of the disease when these signs are due to lymphadenopathy (such as dysphagia, dyspnea). An example could be the treatment of a pregnant mare with retropharyngeal tumor that causes dysphagia, with a view to prolonging the mare’s life until parturition.

**Diseases of the spleen and thymus**

The spleen serves a number of functions—it is a storage organ for blood, a source of extramedullary erythropoiesis in some species, a major component of the reticuloendothelial system, and an important component of the immune system. Its function is most evident in the horse, in which an intact and functioning spleen is necessary for normal work capacity. Blood in the spleen of horses has a hematocrit much higher than that of blood (70-80%) and when relaxed the spleen contains many liters of blood. Excitement or exercise cause splenic contraction through an alpha-1-mediated event and ejection of the red-cell-rich blood into the peripheral circulation, with subsequent marked increases in hematocrit.1 The spleen of an adult horse can eject 5-10 L of blood into the circulation and, together with declines in plasma volume during exercise, increase hematocrit to 55–60% (0.55–0.60 L/L).1

---

**Lymphadenopathy (lymphadenitis)**

Lymph nodes can be enlarged because of inflammation (lymphadenitis) or infiltration with neoplastic cells. Enlargement of peripheral nodes causes visible and palpable swellings and in some cases obstruction to lymphatic drainage and subsequent local edema, as in sporadic lymphangitis of horses. Enlargement of the lymph nodes is a characteristic of infection with Corynebacterium pseudotuberculosis. Lymphadenopathy that causes enlargement of abdominal lymph nodes is a characteristic of infection with S. equi in the burro. Anorectal lymphadenopathy in young horses, causing extraluminal rectal obstruction with colic and sometimes urinary dysfunction. Cervical adenitis (jowl abscess) of pigs, caused principally by group E type IV Streptococcus sp. but also by Actinomyces pyogenes and Pasteurella multocida.

Granulomatous cervical adenitis, which also occurs in pigs and is a common finding at slaughter. The lesions rarely cause clinical illness but are a public health concern because they may be tuberculosis. Most commonly they are associated with Mycobacterium tuberculosis, Mycobacterium avium and Mycobacterium bovis are also causes. Tularemia, infection with Francisella tularensis, in tick-infested sheep. Melioidosis associated with Pseudomonas (Malleomyces) pseudomallei and tick pyemia associated with Staphylococcus aureus in sheep infected with the tick ixodes ricinus. Retropharyngeal lymph node enlargement up to three or four times normal, and colored bright green, have been identified in cattle as resulting from infection with the algae Prototricha spp.3 Tuberculosis. Lymphadenitis in lambs associated with P. multocida, and in some cases of actinobacillosis. Morel’s disease of sheep associated with a micrococcus. Bovine farcy and atypical skin tuberculosis, the latter involving the lymphatics but not associated with lymph node enlargement.

In acute lymphadenitis there may be pain and heat on palpation but the nodes are for the most part painless. Obstructions produced by enlarged lymph nodes can result in secondary signs such as respiratory difficulty with enlargement of the retropharyngeal lymph nodes and esophageal obstruction by enlarged mediastinal lymph nodes. Needle biopsy for cytology and culture can aid in the determination of the cause of lymphadenitis and can allow the differentiation between lymphadenitis and neoplastic enlargement. Ultrasound may also aid in diagnosis. The diseases above are discussed in more detail under their specific headings.

**REFERENCES**

Splenectomy is performed as part of treatment of idiopathic refractory thrombocytopenia, or as a consequence of splenic infarction. Removal of the spleen (splenectomy) impairs the oxygen-carrying capacity of blood during exercise, by preventing the normal increase in hematocrit, and prevents the normal cardiovascular responses to exercise, including increases in right atrial pressure.3,4

**SPLENOMEALGY**

Diffuse diseases of the spleen that result in enlargement are usually secondary to diseases in other organs. Splenomegaly with complete destruction of splenic function is virtually symptomless, especially if the involvement occurs gradually, and in most cases clinical signs are restricted to those caused by involvement of other organs. An enlarged spleen may be palpable on rectal examination in the horse and careful percussion may detect enlargement of the spleen in cattle, but in most instances involvement of the organ is not diagnosed at antemortem examination unless laparotomy is performed. Left dorsal displacement of the colon in the horse is a colic in which the spleen is displaced medially and this may give the impression that the organ is enlarged. Rupture of a grossly enlarged spleen may cause sudden death due to internal hemorrhage. This is sometimes the cause of death in bovine viral leukosis or equine amyloidosis.5 Moderate degrees of splenomegaly occur in many infectious diseases, especially salmonellosis, anthrax, babesiosis, equine infectious anemia and diploplastic septicaemias in calves, and in some noninfectious diseases such as copper toxicity in sheep. Animals that die suddenly include lymphosarcoma, melanoma in horses.6-8 Metastasis of the commonest cause of the disease in large animals and gastric penetration by sharp metal have caused splenitis in the horse. Perforation of a gastric ulcer or an erosion of the gastric wall caused by *Gasterophilus intestinalis*10 or extension of a granuloma caused by larvae of *Habronema* sp. in horses may lead, by extension, to development of a supplicative lesion in the spleen. In those occasional cases of strangles in horses in which systemic spread occurs, splenic abscess occasionally occurs.

Splenic abscesses associated with *C. pseudotuberculosis* infection are diagnosed in horses in those parts of the world where the infection is endemic. The most common clinical signs are concurrent external abscesses, anorexia, fever, lethargy, weight loss and signs of respiratory tract disease or abdominal pain. Clinico-pathological abnormalities included serum synergistic hemolysin inhibition titer of 512 or more, and leukocytosis with neutrophilia, hyperglobulinemia, hyperfibrinogenemia and anemia. Diagnosis is based on the presence of appropriate clinical signs and ultrasonographic examination of the spleen. Prolonged treatment with antimicrobials is successful in most cases.31

If the abscess is extensive and acute there are systemic signs of fever, anorexia and increased heart rate. Pain is evidenced on palpation over the area of the spleen and hematological examination reveals a marked increase in the total white cell count and a distinct shift to the left in the differential count.

Abdominocentesis usually provides evidence of chronic peritonitis by the presence of a large amount of inflammatory exudate. Peritonitis is often coexistent and produces signs of mild abdominal pain with arching of the back and disinclination to move. Mild recurrent colic may also occur. Anemia, with marked pallor of mucousa, and terminal ventral edema are also recorded. The spleen may be sufficiently enlarged to be palpable per rectum.12 Treatment of splenic abscess is often unrewarding because of the extensive nature of the lesion before clinical signs appear. The systemic signs can usually be brought under control by treatment with sulfonamides or antibiotics over a period of about 7 days but relapses are common and death is the almost certain outcome. Splenectomy is recommended if adhesions and associated peritonitis are absent.

**SPLENIC ABSCESS**

Splenic abscess may result when a septic embolus lodges in the spleen, but is more commonly caused by extension of infection from a neighboring organ. Perforation by a foreign body in the reticulum of cattle is the commonest cause of the disease in large animals and gastric penetration by sharp metal have caused splenitis in the horse. Perforation of a gastric ulcer or an erosion of the gastric wall caused by *Gasterophilus intestinalis* or extension of a granuloma caused by larvae of *Habronema* sp. in horses may lead, by extension, to development of a supplicative lesion in the spleen. In those occasional cases of strangles in horses in which systemic spread occurs, splenic abscess occasionally occurs.

Splenectomy is performed as part of treatment of idiopathic refractory thrombocytopenia, or as a consequence of splenic infarction. Removal of the spleen (splenectomy) impairs the oxygen-carrying capacity of blood during exercise, by preventing the normal increase in hematocrit, and prevents the normal cardiovascular responses to exercise, including increases in right atrial pressure.3,4

**SPLENIC HEMATOMA, RUPTURE OR INFARCTION**

Formation of a hematoma in the spleen or, in the more severe instance, splenic rupture usually occurs as a result of trauma. The syndrome is best described in horses, occurring as a result of falling on to a stirrup or blunt trauma to the left side of the rib cage.2,3,13,14 The clinical signs include colic, tachycardia, cold extremities and pallor of the mucous membranes—all, of which are suggestive of hemorrhagic shock. If a hematoma is present ultrasonographic examination of the abdomen will reveal an abnormally shaped spleen containing a hypoechogenic mass. Rupture of the spleen with be apparent as accumulation of a large quantity of fluid within the abdomen. The fluid will have the ultrasonographic characteristics of blood (a swirling echodensity). Laparoscopy can be used to confirm the diagnosis. Hematoma can reveal leukocytosis and low hematocrit. Peritoneal fluid can be serosanguinous if the hematoma has not ruptured, or bloody if the spleen is ruptured.

Infarction of the spleen is reported rarely in horses and so predisposing factors are not identified.15 In other species splenomegaly predispose to infarction. The clinical signs are mild to moderate colic, tachycardia and signs of hemorrhagic shock. Ultrasonography and exploratory laparotomy are diagnostic. The spleen is enlarged and has numerous zones of varying echogenicity, which is in marked contrast to the usual homogenous echogenicity of normal spleen. There can be excessive, echogenic fluid in the abdomen consistent with blood. Treatment is surgical, although technically challenging because of the splenomegaly and risk of rupture of the spleen.

**TREATMENT** of a splenic hematoma is conservative, with enforced rest for a period of up to 3 months. Resolution of the hematoma can be monitored by periodic ultrasonographic examination. Horses with a ruptured spleen usually die within a short period of time. Theoretically, emergency splenectomy might be useful, but timely diagnosis and surgery is difficult to achieve because of the short time course of the disease.

**REFERENCES**

CONGENITAL ANOMALIES

Abdominal situs inversus is reported in a calf. The calf had a rumen that was on the right side of its abdomen, and two spleens, among other abnormalities. The clinical presentation was chronic bloat.

THYMUS

The thymus is the source of T cells in animals and is essential for development of normal immune responses. These functions occur during late gestation and in the neonate. Primary diseases of the thymus are rare in farm animals. The thymus is largest, relative to body size, in neonates and atrophies in adults to the extent that it can be difficult to identify. Aplasia or thymic hypoplasia occurs as part of severe combined immunodeficiency in Arabian foals. Aplasia of the thymus is reported in a Holstein calf. The congenital condition results in increased susceptibility to infection. Extrathoracic thymus tissue occurs in lambs and can be mistaken for enlargement of the thyroid glands. Neoplasia of the thymus occurs in most species. Thymic lymphomas are reported in horses, pigs and calves. Thymoma and thymic carcinoma are reported in horses and cattle. The clinical syndrome is that of a cranial thoracic mass. There can be compression of the cranial vena cava with obstructed blood flow and signs of congestive heart failure. The jugular veins are distended and there can be submandibular edema. There can be accumulation of excessive pleural fluid. Esophageal obstruction evident as bloat in cattle or dysphagia in cattle and horses occurs. Radiography or ultrasonography of the chest demonstrate the mass, and histological diagnosis can be achieved at necropsy or in samples obtained by fine-needle biopsy.

REFERENCES

Immune deficiency disorders (lowered resistance to infection)

Increasingly, animals are encountered that are much more susceptible to infection than their cohorts. These animals may be suffering because of a reduction in their immune function and need to be identified as such. The history and signs that should suggest the possible presence of compromised immune function are:

- Infections developing in the first 6 weeks of life
- Repeated or continuous infections that respond poorly to treatment
- Increased susceptibility to low-grade pathogens and organisms not usually encountered in immunocompetent animals
- Administration of attenuated vaccines leading to systemic illness
- Low leukocyte counts, either generally or as lymphopenia or neutropenia, perhaps within an associated low platelet count.

It is not proposed to detail the mechanisms of humoral and cellular immunity here because there is a large literature based on the subject in immunology. However, it is necessary to remember that the normal immune response is a very complicated process, including many sequential steps, and there are various sites at which defective development or function can occur.

The disorders of immunity may be primary, in which the animal is born with a congenital defect of one of the immune processes, or secondary, in which the animal has a normal complement of immunological processes at birth but suffers a dysfunction of one of them, often temporarily, during later life. Toxicological and microbiological agents can have this effect.

Immunosuppression is a state of temporary or permanent dysfunction of the immune response resulting from damage to the immune system and leading to increased susceptibility to disease agents. In immunosuppression there is decreased immune responsiveness to all foreign antigens, whereas in immune tolerance there is a state of decreased or nonresponsiveness to one particular antigen. Immunosuppression may be associated with infectious and non-infectious agents. A review of the general aspects of immunosuppression and the various agents responsible is available. Infectious agents include bacteria, viruses, protozoa and helminths; noninfectious causes include chemicals, hormones and some antimicrobials such as chlorotetacyclines and toxins. Environmental factors such as extremes of temperature, humidity, high population density and mixing animals from different origins, and prolonged transportation have also been implicated as causes of immunosuppression but the pathogenesis of these has not been well explained.

Various laboratory methods can be used to evaluate immunosuppression. The criteria which can be used to evaluate immune functions include:

- Gross and microscopic changes in the morphology of central or peripheral lymphoid tissues
- Changes in the concentration or ratios of different classes of immunoglobulin
- Changes in serum complement concentration
- Changes in the functional activity of immunoglobulins
- Changes in functional activity of the immune response
- Interference with the results of vaccination
- Exacerbation in the course of disease associated with other agents
- Changes in the number and viability of cells from lymphoid organs.

The development of monoclonal antibody reagents has allowed new approaches to veterinary immunopathology, particularly the identification and analysis of leukocyte subpopulations in health and disease.

Most of the diseases associated with immunological deficiency states are dealt with in systems or other categories of disease throughout this book and only a checklist is provided here.

PRIMARY IMMUNE DEFICIENCIES

The primary immunodeficiencies can be either innate immunity or adaptive immunity. Deficiencies of innate immunity include:

- Chédiak–Higashi syndrome, an inherited defect of many animal species, including cattle. This is a defect of phagocytic capacity via the neutrophils and monocytes
- Bovine leukocyte adhesion deficiency of Holstein calves, which results from a deficiency in CD18 and accumulation of profound numbers of neutrophils in circulation but not in tissue.

Deficiencies of adaptive immunity include:

Combined immunodeficiency (CID) of Arabian horses due to an inherited failure to produce and differentiate lymphoid precursor cells into B and T lymphocytes. See Table 34.2 for a listing of immunodeficiencies of horses. A similar disease is reported in an Angus calf.

Agammaglobulinemia of Standardbred and Thoroughbred horses, a probably inherited failure to produce B lymphocytes. These horses live much longer than those affected with CID.
Secondary immune deficiencies are as follows:

- Selective deficiencies of one or more globulins. A deficiency of IgM in Arabian horses and Quarter horses is listed. IgM and IgA combined deficiencies with diminished but discernible levels of IgG are observed occasionally in horses. A transient hypogammaglobulinemia (absence of IgG) has been reported in one Arabian foal, which was immunodeficient until it was 3 months old and then became normal.

- Selective IgG2 deficiency in Red Danish cattle.

- A syndrome of immunodeficiency in Fell ponies.

- Common variable immunodeficiency is described in adult horses.

- Lethal trait A46 (inherited parakeratosis) of cattle is a primary immunodeficiency influencing T lymphocytes, with impairment of cellular immunity.

- Selective IgG2 deficiency of cattle causes increased susceptibility to gangrenous mastitis and other infections. It is a primary deficiency of IgG2 synthesis, and is recorded in the Red Danish milk breed.

- Sheep and pigs — there are as yet no recognized primary immunodeficiencies in these species.

**SECONDARY IMMUNE DEFICIENCIES**

These are as follows:

- Failure of transfer of passive immunity, i.e. of antibodies from colostrum to the offspring, is well known as the commonest cause of deficient immunity in the newborn and is discussed in Chapter 3.

- Atrophy of lymphoid tissue and resulting lymphopenia associated with:
  - Viral infections such as equine herpes virus in newborn foals, rinderpest, bovine virus diarrhea, swine fever, porcine circovirus and hog cholera. All these cause lymphatic tissue suppression and a diminished immunoresponsiveness. The pathogenesis of the immunodeficiency associated with the bovine viral diarrhea (BVD) virus may be due to impairment of the function of polymorphonuclear cells.
  - Bacterial infections such as Mycoplasma spp. and Mycobacterium paratuberculosis have approximately the same effect as the above.
  - Physiological stress such as birth may cause immunosuppression in the fetus, making it very susceptible to infection in the period immediately after birth. There is a similar depression of immunological efficiency in the dam immediately after parturition, which, for example, leads to periparturient rise of worm infestation in ewes. Psychological stress in experimental animals does increase susceptibility to infection, but the practical importance of this to animal production is not clear.
  - Toxins such as bracken, tetrachlorethylene-extracted soybean meal, T2 mycotoxin and atomic irradiation suppress leukopoiesis. Immunosuppression is also attributed to many environmental pollutants, including polychlorinated biphenyls, 2,4,5-T contaminants, 2,4,5-T contaminants, DDT, aflatoxin and the heavy metals.
  - General suppression of immune system responsiveness, e.g.:
    - Glucocorticoids administered in large doses or over long periods reduce the activity of neutrophils and the number of circulating lymphocytes, although the reduction varies widely between species. The production of antibodies is also reduced.
    - Nutritional deficiency, especially of zinc, pantothenic acid, calcium and vitamin E, cause general suppression. A total caloric deficiency has a similar effect. Addition of certain trace elements such as copper, iron, zinc and selenium in animal feeds is necessary for an adequate immunity. Selenium, alone or in combination with vitamin E, can enhance antibody responses, whereas its deficiency results in immunosuppression. Selenium supplementation in animal feeds is important to enhance both antibody production and phagocytic activity of neutrophils. In cattle, copper deficiency induced by molybdenum or iron can cause an impairment in the ability of neutrophils to kill ingested Candida albicans. A review of the influence of immunoenhancing vitamins in cattle is available. Nutrients that stimulate disease resistance include carotenoids, vitamins A, E, and C, zinc, manganese, copper and selenium. Neonatal calves may have low reserves of carotene and vitamins A and E and are dependent upon obtaining them from colostrum, which contains highly variable quantities. Administration of drugs that impair folate metabolism can induce anemia and depletion of white blood cells, with subsequent bacterial infection.
    - Experimentally, a protein-energy malnutrition in neonatal calves results in loss of body weight, and decreased lymphocyte interleukin-2 activity and lymphocyte proliferation when compared to calves of similar age.
    - Exposure to cold and heat stress for periods of several weeks duration.
    - Events associated with parturition, in particular glucocorticoid release, that impair innate immunity.

**Amyloidoses**

The amyloidoses are a group of diseases characterized by the deposition of an extracellular proteinaceous substance, amyloid, in the tissues with subsequent disruption of normal tissue architecture leading eventually to organ dysfunction. Amyloidosis in farm animals usually occurs in association with a chronic suppurative process elsewhere in the body and is due to accumulation of AA amyloid. Another form of the disease involves accumulation of AL amyloid, especially as localized disease in horses.

**ETIOLOGY AND EPIDEMIOLOGY**

Amyloidosis occurs rarely and when it does occur it is most common in animals exposed systemically and repeatedly to antigenic substances. Examples include repeated injections of antigenic material for commercial production of hyperimmune serum and long-standing suppurative diseases or recurrent infection as in Chédiak–Higashi syndrome. Severe strongylid parasitism in the horse has been reported as a cause. Holstein calves with bovine leukocyte adhesion deficiency have accumulation of amyloid in tissue, although this is not the primary disease. Many cases of amyloidosis in large animals are without apparent cause.

The incidence of visceral AA amyloidosis in slaughtered cattle in a group of
302 cattle older than 4 years of age in Japan was 5.0% compared with those previously reported from Japan and other countries ranging from 0.4-2.7%. Systemic AA-amyloidosis associated with tuberculous has been described in a European wild boar. Systemic amyloidosis in goat kids with chronic arthritis associated with seroconversion to Erysipelothrix rhusiopathiae has been described.

Out of 16 000 horses referred for clinical examination into a veterinary teaching hospital over a period of 13 years, nine horses were identified with amyloidosis. Cutaneous amyloidosis has been associated with malignant histiocytic lymphoma in the horse.

A case of cardiac amyloidosis causing heart failure in a 16-year-old Thoroughbred gelding has been described. The disease was due to accumulation of AL amyloid. The AL form of amyloidosis is characteristically associated with unstable monoclonal immunoglobulin light chains produced by plasma cell dyscrasia and resulting in deposition of AL fibrils.

**PATHOGENESIS**

How amyloid is formed is uncertain but a hyperglobulinemia is commonly present and this, together with the circumstances under which it occurs, suggest an abnormality of the antigen–antibody reaction. Amyloidoses are classified by the types of amyloid protein deposited. AA amyloid is derived from serum amyloid-A protein (SAA), which is an acute-phase reactant produced by hepatocytes. However, increased concentrations of SAA alone are not sufficient to cause amyloidosis. AA (secondary) amyloidosis is associated with recurrent acute or chronic infections, inflammatory disease or neoplasia.

Extensive amyloid deposits may occur in the spleen, liver or kidneys and cause major enlargement of these organs and serious depression of their functions. The commonest form that is clinically recognizable in animals is renal amyloidosis. This presents as a nephrotic syndrome with massive proteinuria and a consequent hypoproteinemia and edema. Temporally, the animal is uremic, becoming comatose and recumbent. The edema of the gut wall and its infiltration with amyloid create the conditions necessary for the development of diarrhea. In horses, cases of multiple cutaneous lesions are recorded. The amyloid is present in 5–25 mm diameter nodes in the skin of the head, neck and pectoral regions.

Rare cases of involvement of the upper respiratory tract (nasal cavities, pharynx, larynx, guttural pouch and lymph nodes of the head and neck, and conjunctiva) are also recorded in horses. The amyloid material deposited in the tissues is usually of the AL form, whereas systemic disease is almost always the AA form.

**AL amyloidosis** is also reported in an adult cow with bovine leukocyte adhesion deficiency.

**CLINICAL FINDINGS**

Many cases of amyloidosis are detected incidentally at necropsy. The cutaneous form in horses is characterized by the presence of hard, nonpainful, chronic plaques in the skin. Most of the lesions, which can be widespread and severe, are on the sides of the neck, shoulders and head. Respiratory tract involvement in the horse is usually limited to the nasal cavities, and this may cause dyspnea.

Chronic heart failure due to cardiac amyloidosis secondary to systemic amyloidosis in a 16-year-old gelding was characterized clinically by weight loss, dysphagia, recurrent episodes of esophageal obstruction and anorexia of a few weeks duration. Ventral edema, tachycardia and irregular heart rate associated with atrial fibrillation were present. The clinical findings were consistent with biventricular heart failure from ventricular dysfunction, atrial fibrillation and pulmonary hypertension. The amyloid was of the AL form.

A case of systemic AL amyloidosis associated with multiple myeloma in a horse was characterized clinically by rapid weight loss, muscle atrophy, soft unformed feces and ventral edema.

Hemoperitoneum and acute death secondary to splenic or hepatic rupture in horses with systemic amyloidosis is reported.

Clinical cases in cattle are characterized by emaciation and enlargement of the spleen, liver or kidneys; involvement of the kidney causes proteinuria and is often accompanied by profuse, chronic diarrhea, polydipsia and anasarca. In cattle the grossly enlarged left kidney is usually palpable per rectum. Cases may occur within 2 weeks of calving. They are characterized by anorexia, watery diarrhea, anasarca, rapid emaciation and death in 2–5 weeks.

Corpora amylacea are small, round concretions of amyloid material found in mammary tissue of cows. They are usually inert but may cause blockage of the teat canal.

**CLINICAL PATHOLOGY**

An extreme, persistent proteinuria should suggest the presence of renal amyloidosis. Electrophoretic studies of serum may be of value in determining the presence of hyperglobulinemia. Alpha-globulin levels are usually elevated and albumin levels depressed. Horses with hepatic amyloidosis have elevated activities of gamma-glutamyltransferase and, to a lesser extent, bile acids. In cattle there is hypocalcemia, hyperfibrinogenemia, hypomagnesemia, high serum urea and creatinine concentration, low-specific-gravity urine and prolongation of the bromsulfalein clearance time. Biopsy of cutaneous plaques is an accurate diagnostic technique.

**NECROPSY FINDINGS**

Affected organs are grossly enlarged and have a pale, waxy appearance. In the spleen, the deposits are circumscribed; in the liver and kidneys they are diffuse. In a horse with systemic AL amyloidosis associated with multiple myeloma, diffuse gastrointestinal hemorrhage, thickened jejunal mucosa and splenomegaly were present.

The pathology of AA amyloidosis in domestic sheep and goats has been described. Most sheep had pneumonia and other sites of chronic inflammation. Amyloid was detected in all grossly affected kidneys using Congo red staining. Deposits of amyloid in tissues may be made visible by staining with aqueous iodine. Amyloid is detected as green birefringence of Congo-Red-stained tissues viewed under polarized light. AA and AL amyloidosis can be differentiated by treatment of tissue sections with potassium permanganate. Tissue containing AA will lose its green birefringence after treatment with potassium permanganate whereas tissue containing AL will continue to appear green after Congo Red staining and viewing under polarized light.

The Shtrasburg method is now available for the identification of AA amyloid and to distinguish it from amyloid types in a large number of domestic and wild animals.

**DIFFERENTIAL DIAGNOSIS**

Enlargement of parenchymatous organs associated with chronic supplicative processes should arouse suspicion of amyloidosis, especially if there is emaciation and marked proteinuria. Pyelonephritis, nonspecific nephritis and nephrosis bear a clinical similarity to amyloidosis.

**TREATMENT**

There is no effective treatment of the systemic disease. The localized disease as occurs in the upper respiratory tract of horses can be treated by surgical excision, but the results are not encouraging.

Principles of respiratory insufficiency

The principal function of the respiratory system is gas exchange in which oxygen is transferred from the environment to the blood and carbon dioxide is moved in the opposite direction. Other important functions include a role in thermoregulation in most species, acid–base regulation in concert with the kidney, as an endocrine organ (e.g. angiotensin-converting enzyme), in the metabolism of metabolically active substances, including eicosanoids and nitric oxide, and in the immune response to inhaled immunogens and pathogens. Capillaries in the lungs of the farm animal species and horses also possess intravascular macrophages, which are important as a reticuloendothelial organ in the processing of antigens – an action achieved by similar cells in the liver of dogs, cats, and humans. Interference with these functions can occur in a number of ways and can have a variety of manifestations that are apparent during disease. The most readily apparent failure of the respiratory system is failure of gas exchange with resultant hypoxemia and hypercapnia. However, failure of other functions of the respiratory system can also result in clinically apparent disease.

Failure of gas exchange, and the resultant hypoxia and hypercapnia, is responsible for most of the clinical signs of respiratory disease and for respiratory failure, the terminal event of fatal cases. Death due to respiratory failure is due to hypoxia. An understanding of hypoxia, hypercapnia and respiratory failure is essential to the study of clinical respiratory disease.

DEFINITIONS

A number of terms are used to describe the function of the respiratory tract, or abnormalities that arise because of a variety of diseases. Many of these terms are described in more detail in the text that follows, but a brief definition of each is provided here:

- Hypoxia is a broad term meaning diminished availability of oxygen to tissues
- Hypoxemia is deficient oxygenation of blood, usually assessed by measurement of blood oxygen tension, or by measurement of blood hemoglobin saturation and hemoglobin concentration, and subsequent calculation of blood oxygen content
- Hypercapnia is an abnormally high carbon dioxide tension in blood
- \( P_{\text{O}_2} \) is the oxygen tension (partial pressure) in arterial blood
- \( P_{\text{A}_2} \) is the oxygen partial pressure in alveolar gas
- \( P_{\text{CO}_2} \) is the carbon dioxide tension in arterial blood
- \( P_{\text{ECO}_2} \) is the carbon dioxide partial pressure in alveolar air
- \( C_{\text{O}_2} \) is the arterial oxygen content (milliliters of \( \text{O}_2 \) per 100 mL of blood)
- \( P_{\text{O}_2} \) is the oxygen tension (partial pressure) in venous blood
- \( P_{\text{CO}_2} \) is the carbon dioxide tension in venous blood

...
HYPOXIA

Failure of the tissues to receive an adequate supply of oxygen occurs in a number of ways and the differences are clinically relevant, in that they are associated with failure of different organ systems, different diseases, and have fundamentally different pathophysiological mechanisms.

Hypoxic (or hypoxemic) hypoxia

Hypoxic (or hypoxemic) hypoxia occurs when there is inadequate oxygenation of blood (hypoxemia) and is usually associated with disease of the respiratory tract or other causes of hypoventilation. Situations in which there is inadequate oxygenation of blood in the lungs include hypoventilation, ventilation/perfusion mismatches, diffusion impairment, low inspired oxygen tension and extrapulmonary right-to-left shunting.

Hypventilation occurs in animals with depressed consciousness, such as occurs with general anesthesia and heavy sedation, or in newborns, in which the central respiratory drive is suppressed.

Airway obstruction caused by the presence of foreign bodies in the airway, luminal obstruction by masses, such as retropharyngeal abscesses in horses with strangles, laryngeal spasm or bronchocstriction can cause inadequate alveolar ventilation and hypoxemia. Diseases that prevent adequate inflation of lungs cause alveolar hypoventilation and the consequent hypoxemia. These diseases include pneumothorax, pleural effusion or respiratory muscle weakness, such as can occur with botulism, tick paralysis, tetanus, strychnine poisoning or severe white muscle disease.

Ventilation/perfusion (V/Q) mismatches occur when the distribution of blood flow in the lungs does not match the distribution of alveolar ventilation, with the result that areas of lung that are well ventilated are not adequately perfused and those areas that are well perfused by blood are not well ventilated. Ventilation/perfusion mismatches are the most important cause of hypoxemia in many lung diseases, including pneumonia.

Diffusion impairment occurs when there is decreased transfer of oxygen from alveolar air that has a normal $P_{a}O_{2}$ to red blood cells in alveolar capillaries because of: increased distance of diffusion through the alveolar membranes, such as might occur with pulmonary edema; decreased surface area available for diffusion, such as occurs with positional atelectasis or pulmonary embolism; or decreased transit time of red cells through the alveolar capillaries, such as occurs in horses during heavy exercise.

Low inspired oxygen tension occurs naturally only in animals at high altitude. It can also occur during anesthesia if there are defects in the ventilator causing low oxygen tension in the gases delivered to the animal.

Extrapulmonary right-to-left shunting occurs most commonly as a vascular defect (see Ch. 8).

The actual cause of hypoxemia in an individual animal or disease is often multifactorial and not simply a result of one of the mechanisms described above. For instance, cows placed in dorsal recumbency during general anesthesia become hypoxic because of compression of the thorax by the abdominal viscera, thereby causing hypoventilation and compression atelectasis with diffusion impairment, ventilation/perfusion mismatching and reduced cardiac output because of reduced venous return.

Anemic hypoxia

Anemic hypoxia occurs when there is a deficiency of hemoglobin per unit volume of blood (anemia). The percentage saturation of the available hemoglobin and the oxygen tension of arterial blood are normal but as a result of the low hemoglobin concentration the oxygen-carrying capacity of the blood is reduced. Anemia due to any cause has these characteristics. The decrease in oxygen-carrying capacity caused by a 50% reduction in hemoglobin concentration from normal values (from 20 g/dL to 10 g/dL) is much greater than the decrease that results from a 50% reduction in arterial oxygen tension from normal (e.g. a reduction from 100 mmHg to 50 mmHg).

Alteration of hemoglobin to pigments, such as methemoglobin or carboxyhemoglobin, that are not capable of carrying oxygen has the same effect on oxygen content as anemia. Thus in poisoning caused by nitrite, in which hemoglobin is converted to methemoglobin, and in that due to carbon monoxide, when the hemoglobin is converted to carboxyhemoglobin, there is hypoxia due to inadequate oxygenation of blood.

Circulatory hypoxia

Circulatory hypoxia occurs as a result of inadequate delivery of oxygen to tissue because of inadequate perfusion of tissues by blood. The blood is usually adequately oxygenated but blood flow rate to tissues is not, and therefore the rate at which it delivers oxygen to tissue is less than the amount of oxygen required to support the metabolic function of that tissue. In other words, the rate of delivery of oxygen to tissue does not match the metabolic requirements of that tissue. A common cause of this is low cardiac output, such as occurs with congestive heart failure or hypovolemic shock. It also occurs with local interruption to arterial flow such as the thrombotic embolism of thromboembolic colic of horses or compression of vessels, such as in right displacement and torsion of the abomasum.

Histotoxic anoxia

Histotoxic anoxia occurs when oxygen delivery to tissue is adequate because both oxygen content of arterial blood and blood flow are appropriate, but the tissue is unable to utilize oxygen. Cyanide poisoning is the only common cause of this form of anoxia.

Consequences of hypoxia

Consequences of inadequate delivery of oxygen include changes in almost all body systems. The central nervous system and heart are most susceptible to the immediate and acute effects of hypoxia, whereas clinical signs related to hypoxic damage to the gastrointestinal tract and kidneys are somewhat delayed. Central nervous system hypoxia is evident as mild changes in mentation, such as depression, progressing through decreased alertness to coma and death. Cardiac changes include a reduction in the force and efficiency of contraction due to impaired myocardial contractility, and an increased susceptibility to arrhythmia. The kidney, gut and liver are all metabolically active tissues and therefore susceptible to hypoxia. Renal function is reduced during hypoxia, with the renal medulla being most sensitive to decreases in oxygen delivery. Signs of gastrointestinal dysfunction during hypoxia include ileus, abdominal pain and abdominal distension due to accumulation of gas and liquid in the gastrointestinal tract. Liver dysfunction can be evident as decreases in blood glucose concentration and increases in serum activity of liver-derived enzymes (alkaline phosphatase, gamma-glutamyl transpeptidase, sorbitol (inositol) dehydrogenase) and metabolites ( bile acids, bilirubin).

Some metabolically active tissues, when deprived of oxygen, use anaerobic metabolism to sustain energy supply for
short periods of time (depending on the tissue, but the brain cannot survive without oxygen for more than 2–3 min). Use of anaerobic glycolysis for energy causes metabolic acidosis. Animals in respiratory failure therefore often have a mixed acid–base disturbance characterized by metabolic and respiratory acidosis.

COMPENSATORY MECHANISMS

Compensation of respiratory insufficiency occurs as both short-term and long-term events. Short-term compensatory mechanisms for low arterial oxygen tension or oxygen delivery to tissues occur within seconds to minutes and include respiratory, cardiovascular and behavioral responses. Stimulation of respiratory centers in the medulla oblongata by low arterial oxygen tension (P(\text{O}_2)) and high arterial carbon dioxide tension (P(\text{CO}_2)) causes an increase in respiratory minute volume mediated by an increase in tidal volume and respiratory frequency. Both low oxygen tension and high carbon dioxide tension in arterial blood, together or separately, are potent stimulators of these events. Inadequate tissue oxygenation also stimulates an increase in cardiac output, mainly as a result of increased heart rate and to a lesser extent by an increase in stroke volume. Splenic contraction, in those species such as the horse in which the spleen is an important reservoir of red blood cells, increases both blood volume and hemoglobin concentration, thereby increasing the oxygen-carrying capacity of blood. Hypoxemia also causes animals to attempt to decrease their oxygen requirement by decreasing physical activity, including moving and eating.

Longer-term compensatory mechanisms include an increase in erythropoietin secretion by the kidney by sudden increases in bone marrow production of red blood cells and an increase in hemoglobin concentration in blood. This polycythemia increases the oxygen-carrying capacity of blood. Severe polycythemia, such as occurs with congenital cardiac anomalies causing chronic right-to-left shunting, increases the viscosity of blood and impairs tissue perfusion, increases the workload of the heart and the risk of thromboembolism. Longer-term compensatory mechanisms also include changes in ventilatory pattern, such as in horses with heaves, and behavior.

CARBON DIOXIDE RETENTION (HYPERCAPNIA)

Respiratory insufficiency results in decreased elimination of carbon dioxide and its accumulation in blood and tissues. Animals breathing room air that are hypercapnic are always hypoxemic. Increasing the oxygen tension of inspired air can alleviate the hypoxemia but, by reducing hypoxic stimulation of the respiratory center, can cause further increments in arterial \( P(\text{CO}_2) \).

Acute hypercapnia causes a respiratory acidosis that reduces both blood and cerebrospinal fluid pH.\(^2\) The clinical signs of acute hypercapnia are initial anxiety followed by central nervous system depression and eventual coma and death. These clinical abnormalities are attributable to declines in the pH of cerebrospinal fluid (CSF), a consequence of the ease with which carbon dioxide crosses the blood–brain barrier. Decreases in CSF pH are greater for respiratory acidosis than for a similar degree of metabolic acidosis. Severe hypercapnia also causes peripheral vasodilation, which can contribute to arterial hypotension, and cardiac arrhythmia. The acid–base effects of chronic hypercapnia are compensated by renal mechanisms that return the arterial and CSF pH to almost normal and therefore do not cause more than mild clinical disease in most instances. So long as oxygen delivery to tissue is maintained, animals can tolerate quite high arterial carbon dioxide tensions for a number of days or longer – this is referred to as ‘permissive hypercapnia’ and is sometimes an alternative to artificial or mechanical ventilation of animals with respiratory insufficiency.

RESPIRATORY FAILURE

Respiratory movements are involuntary and are stimulated and modified by the respiratory centers in the medulla. The centers appear, at least in some species, to have spontaneous activity that is modified by afferent impulses to higher centers, including: cerebral cortex and the heat-regulating center in the hypothalamus; from the stretch receptors in the lungs via the pulmonary vagus nerves; and from the chemoreceptors in the carotid bodies. The activity of the center is also regulated directly by the pH and oxygen and carbon dioxide tensions of the cranial arterial blood supply. Stimulation of almost all afferent nerves may also cause reflex change in respiration, stimulation of pain fibers being particularly effective.

Respiratory failure is the terminal stage of respiratory insufficiency in which the activity of the respiratory centers diminishes to the point where movements of respiratory muscles cease. Respiratory failure can be paralytic, dyspneic or asphyxial, or tachypneic, depending on the primary disease.

The respiratory failure that occurs in animals with pneumonia, pulmonary edema and upper respiratory tract obstruction is caused by combinations of hypoventilation, ventilation/perfusion mismatch and diffusion impairment, which leads to hypercapnia and hypoxemia. Hypercapnia and hypoxia stimulate the respiratory center and there is a potent respiratory drive evident as markedly increased respiratory rate and effort. As the disease progresses these changes become more marked until death occurs as a result of central nervous system or cardiac failure. Animals that die of the central nervous system effects of respiratory failure typically have dyspnea followed by periods of gasping and apnea just before death.

Paralytic respiratory failure is caused by depression of the respiratory centers or paralysis of the muscles of respiration. Depression of the respiratory center occurs with poisoning by respiratory center depressants, such as general anesthetics, or damage to the respiratory center, such as might occur with brain-stem injury. Paralysis of respiratory muscles occurs in disease such as botulism, tetanus, strychnine poisoning, white muscle disease, severe hypocalcemia and tick paralysis. The signs of paralytic respiratory failure are a gradual or abrupt cessation of respiratory movements without preceding signs of increased respiratory effort or dyspnea. The animal is often unconscious, or unable to move, during the later stages of the disease.

The differentiation of these types of failure is of some importance in determining the type of treatment necessary. In the paralytic form of respiratory failure the optimal treatment is mechanical ventilation, along with removal of the inciting cause. Administration of respiratory stimulants is seldom effective as sole therapy. The more complex pathogenesis of respiratory failure in most diseases requires a therapeutic approach that removes each of the underlying defects. In most cases this is achieved by treating the inciting disease, for example administering antimicrobials to an animal with pneumonia or furosemide to an animal with pulmonary edema, in addition to supportive care including, potentially, nasal or pharyngeal insufflation with oxygen, or mechanical ventilation.

Principal manifestations of respiratory insufficiency

Respiratory disease is evident as one or more of a variety of signs detectable on clinical examination. The signs vary with the etiology of the disease and its anatomic location. Diseases that impair...
ventilation or gas exchange have hypoxemia and hypercapnia as prominent life-threatening abnormalities. Infectious and inflammatory diseases can cause prominent clinical abnormalities as a result of a systemic inflammatory response and toxemia. The toxemia may be so severe (e.g., in calf diphtheria, aspiration pneumonia and equine pleuritis) as to cause death even though oxygen and carbon dioxide exchange are not greatly impaired. The common signs of respiratory disease are:

- Abnormalities in the rate, depth, or ease of breathing
- Lethargy or exercise intolerance
- Abnormal posture
- Abnormal lung sounds
- Abnormal respiratory noises
- Coughing
- Cyanosis
- Nasal discharge
- Epistaxis and hemothysis.

**ABNORMALITIES IN RATE, DEPTH AND EASE OF BREATHING**

**Polypnea** is a rate of breathing that is faster than observed in clinically normal animals of the same species, breed, age, sex and reproductive status in a similar environment.

**Tachypnea** also describes an increased rate of breathing, although with the implication that breathing is shallow (i.e. of a reduced tidal volume).

**Hyperpnea** is an abnormal increase in the rate and depth of breathing (an abnormally high minute volume) but the breathing is not labored and is not associated with signs from which one could infer represent distress on the part of the animal (i.e. the animal is not dyspneic). This assessment requires measurement of minute ventilation or arterial blood gas tensions.

Dyspnea is a term borrowed from human medicine, in which it refers to the sensation of shortness of breath or air hunger. It is used in veterinary medicine to describe labored or difficult breathing in animals that also display some signs of distress, such as anxious expression, unusual posture or stance, or unusual behavior.

Dyspnea is a physiological occurrence after strenuous exercise and is abnormal only when it occurs at rest or with little exercise. It is usually caused by hypoxia with or without hypercapnia, arising most commonly from diseases of the respiratory tract. In pulmonary dyspnea one other factor may be of contributory importance; there may be an abnormally sensitive Hering–Breuer reflex. This is most likely to occur when there is inflammation or congestion of the lungs or pleura. Rapid, shallow breathing results.

**Expiratory dyspnea** is prolonged and forceful expiration, usually associated with diffuse or advanced obstructive lower airway disease. The dyspnea of pulmonary emphysema is characteristically expiratory in form and is caused by anoxic anoxia and the need for forced expiration to achieve successful expulsion of the tidal air. It is commonly accompanied by an audible expiratory grunt in ruminants but less so in pigs and almost never in horses.

**Inspiratory dyspnea** is prolonged and forceful inspiration due to obstruction of the extrathoracic airways, such as with laryngeal obstruction or collapse of the cervical trachea. It may also be associated with abnormalities that restrict thoracic expansion, such as restrictive lung diseases and space-occupying lesions of the thorax. It is accompanied by a stridor or loud harsh sound on inspiration when the cause is obstruction of the extrathoracic airways, such as is typical of laryngeal or tracheal disease.

**Open-mouth breathing** is labored breathing with the mouth held open, commonly with the tongue protruded in ruminants and most commonly associated with advanced pulmonary disease or obstruction of the nasal cavities.

**DISEASES CAUSING DYSPNEA AT REST OR LACK OF EXERCISE TOLERANCE**

Dyspnea, along with hypoxemia and hypercapnia, are the clinical and laboratory findings most likely to attract attention to the possible presence of disease in the respiratory system. A brief summary of the causes of dyspnea is outlined in Figure 10.1. It is most important, when attempting to differentiate diseases that cause dyspnea, to include diseases of systems other than the respiratory system that can result in dyspnea. Dyspnea at rest is usually, but not always, caused by respiratory tract disease, whereas exercise intolerance can be caused by disease in the respiratory, cardiovascular, musculoskeletal and other body systems.

**Respiratory tract disease**

Respiratory tract diseases interfere with normal gas transfer, through the mechanisms discussed above. Characteristics of respiratory disease that lead to dyspnea or lack of exercise tolerance include:

- **Flooding of alveoli with inflammatory cells** and/or protein-rich fluid — pneumonia and pulmonary edema
- **Atelectasis** (collapsed alveoli and small airways) — pleural effusion, hemothorax, hydrothorax, pneumothorax, chylothorax, pyothorax, prolonged recumbency of
large animals and diaphragmatic hernia

- **Airway obstruction** – nasal obstruction, pharyngeal/laryngeal obstruction, tracheal/bronchial obstruction, bronchoconstriction and bronchiolar obstruction.

**Cardiovascular disease**

This causes inadequate perfusion of tissues including the lungs. There is reduced oxygen delivery to tissues, even in the presence of normal arterial oxygenation:

- **Cardiac disease**: Cardiac dyspnea results from heart failure and is multifactorial. In animals with dyspnea attributable to cardiac disease there are other readily evident signs of heart failure
- **Peripheral circulatory failure** – usually due to hypovolemic shock, although shock associated with toxemia, including endotoxemia, can cause dyspnea. There are always other prominent signs of disease.

**Diseases of the blood**

These cause inadequate delivery of oxygen to tissues because of anemia or presence of hemoglobin that is unable to carry oxygen.

- **Anemia** – an abnormally low concentration of hemoglobin
- **Altered hemoglobin** – methemoglobinemia (e.g. in nitrite poisoning of cattle, red maple toxicosis of horses), carboxyhemoglobinemia.

**Nervous system diseases**

Diseases of the nervous system affect respiratory function by one of several mechanisms:

- **Paralysis of respiratory muscles** occurs in tick paralysis or botulism. Tetanic spasm of respiratory muscles, such as in tetanus or strychnine toxicosis, also impairs or prevents alveolar ventilation. Both faccicd and tetanic paralysis cause hypercapnia and hypoxemia and, in extreme situations, death by suffocation
- **Paralysis of the respiratory center**, as in poisoning by nicotine sulfate, or overall central nervous system depression, causes hypoventilation because of impaired ventilatory drive
- **Stimulation of the respiratory center**, so-called neurogenic dyspnea, occurs as a result of stimulation of the center by a small irritative lesion, such as in animals with encephalitis, or administration of drugs, such as lobeline, that increase sensitivity of the respiratory center to hypoxemia or hypercapnia.

**Musculoskeletal diseases**

- **Muscle diseases**: Diseases of the respiratory muscles can impair ventilation. These include white muscle disease in lambs, calves, and foals, and some congenital diseases (such as glycogen branching enzyme deficiency in foals)
- **Fatigue**: Animals with primary severe respiratory disease can develop fatigue of the respiratory muscles (intercostal, diaphragm, accessory muscles of respiration), which can further impair ventilation
- **Trauma**: Fractured ribs can impair ventilation both because of the pain of breathing and because of mechanical disruption to respiration (flail chest).

**General systemic states**

Tachypnea can occur in a number of systemic states in which there is no lesion of the respiratory tract or nervous system. These include:

- **Pain** – such as in horses with colic
- **Hyperthermia** – as can occur with intense or strenuous exercise
- **Acidoses** – as a metabolic disturbance associated with any of a number of diseases but notably gastrointestinal disease that causes excessive loss of cationic electrolytes in feces.

**Environmental causes**

- Low inspired oxygen tension, such as in animals at high altitude
- Exposure to toxic gases.

**Miscellaneous poisons**

A number of poisons cause dyspnea as a prominent sign, but in most cases the pathogenesis has not been identified.

- Farm chemicals, including metaldehyde and dinitrophenols (probable mechanism is stimulation of respiratory center)
- Organophosphates and carbamates (probable mechanism is alteration of pulmonary epithelium), urea (probably effective as ammonia poisoning)
- Nicotine depressing the respiratory center
- Poisonous plants, including fast-death factor of algae, the weeds Albizia, Helenium, Eupatorium, Ipomoea, Taxus spp. and Laburnum and ironwood (Erythrophleum spp.); all appear to act at least in part by central stimulation.

**ABNORMAL POSTURE**

Animals with respiratory disease, and especially those in respiratory distress, often adopt an unusual posture and are rarely recumbent except in the terminal stages of the disease. Animals in severe respiratory distress will stand with the head and neck held low and extended. Animals, except horses, will often have open-mouthed breathing. Horses, except in extreme and unusual circumstances, are unable to breathe through the mouth because of the anatomical arrangement of the soft palate, which effectively provides an airtight barrier between the oropharynx and nasopharynx. Cattle with severe respiratory distress and open-mouthed breathing will often drool large quantities of saliva – probably a consequence of decreased frequency of swallowing as the animal labors to breathe.

The positioning of the legs is often abnormal. Severely affected animals, and those with pleuritic pain (horses or cattle with pleuritis) or severe respiratory distress, will usually stand with elbows (humeral radial joint) abducted. The animals are reluctant to move but when forced to do so can react violently. They are resistant to diagnostic or therapeutic interventions that interfere even transiently with their ability to breathe.

**NORMAL AND ABNORMAL BREATH SOUNDS**

Auscultation of the lungs and air passages is the most critical of the physical examinations made of the respiratory system. The examination should be performed in as quiet an environment as possible, though it is often difficult to achieve a silent listening environment in large animal practice. The animal should be adequately restrained so that the examiner can concentrate on the lung sounds, and should not be sedated or anesthetized because of the depression in lung sounds that can occur in these instances. To be effective and diagnostically reliable, auscultation must be systematic. Both the upper and lower parts of the respiratory tract must be examined in every case. It is preferable to begin the examination by auscultating the larynx, trachea and the area of the tracheal bifurcation in order to assess the rate of air flow and the volume of air sound to be heard over the lungs.

**GENERATION OF BREATH SOUNDS**

The animal must be breathing to generate lung sounds. The lung sounds are generated by movement of air in the large and mid-sized airways, including the trachea and bronchi. The greater the velocity of air in the airways, the louder the noise, explaining the loud sounds that are generated in the trachea. Air movement in the bronchioles, terminal airways and alveoli is silent because of the large combined cross-sectional area of these airways and consequent low velocity of air movement and laminar character of the airflow. Sound is generated by...
turbulent airflow and the degree of turbulence is affected by the velocity of airflow and the diameter of the airway. This sound is then transmitted through the lung and chest wall to the surface of the thorax, where it can be detected by use of a stethoscope.

Quiet breath sounds can be a result of low tidal volume with resultant low velocity of airflow, or impaired transmission of sounds to the surface of the chest. Sound is transmitted most readily through dense liquids such as water. Most tissue, except fat, is approximately 70% water and transmits sounds readily. Sound is reflected at the interface of two media of markedly different densities—such as air and tissue—and less sound is transmitted. Thus, in the normal lung there is marked attenuation (softening) of breath sounds because of the extensive air–tissue interfaces. This is evident by comparing the intensity of breath sounds heard over the trachea to those heard over the chest wall. However, lung sounds are more readily transmitted when areas of the lung do not contain air, such as occurs with atelectasis, pulmonary edema or infiltration of lung by inflammatory exudates. Sounds generated in the large airways are more readily transmitted through this consolidated tissue and are evident at the chest wall as louder bronchial breath sounds. The presence of bronchial breath sounds that are audible on the chest surface is dependent upon the presence of a patent bronchus with airflow to generate the lung sounds and of tissue that readily transmits the sounds generated in the bronchus. Lung sounds will not be heard if they are not generated (as a result of lack of airflow in bronchi) or are muffled by extensive accumulations of fluid or fat between the lung and the chest wall. Lung sounds are reduced in animals with airflow of low velocity in large airways, such as occurs in animals with low tidal volumes, or in which there is obliteration of the bronchial lumen by fluid or tissue. Low tidal volumes occur in animals at rest or in those in which there is rapid but shallow (low tidal volume) breathing. Obliteration of the bronchial lumen occurs in many diseases, including pneumonia.

REBREATHING (‘BAGGING’) EXAMINATION

Detection of abnormal lungs sounds is optimized by increasing the animal’s tidal volume, and thereby the velocity of airflow in large airways. An expeditious means of temporarily increasing the animal’s tidal volume is to occlude the nostrils for a brief period (30–60 s). When the animal is again allowed to breathe it will take several large, deep breaths, during which lung sounds can be auscultated. However, the increase in tidal volume is transient and does not permit time for detailed auscultation of the chest. A preferred technique is to place an air-tight bag over the animal’s muzzle such that all the air that it inhales is contained within the bag. The volume of air in the bag should exceed the anticipated stimulated tidal volume of the animal. As a rule of thumb, the volume of the bag should be sufficient to allow the animal a tidal volume of 10–15 mL of air per kilogram of body weight (BW). A 500 kg horse or cow therefore needs a bag that contains 10 L of air. Hyperventilation is stimulated by an increase in carbon dioxide content of inspired air with subsequent hypercapnia and stimulation of the respiratory center. A more refined technique has the animal inhaling gas that is 5% carbon dioxide and 95% oxygen, thereby preventing hypoxemia due to the examination. Rebreathing examinations (or ‘bagging’) are not indicated if abnormal lung sounds are detected on initial examination as the results of the rebreathing examination will not add any additional information. Animals in respiratory distress should not be subjected to a rebreathing examination because it might worsen the hypoxemia or hypercapnia already present, and is inhumane. Rebreathing examinations are indicated when respiratory disease is suspected but initial auscultation of the thorax does not reveal abnormal lung sounds.

INTERPRETATION OF BREATH SOUNDS

Terminology used to describe normal and abnormal lung sounds is now well established and should be used consistently so that it is a useful diagnostic aid.4,5 Associations between abnormal respiratory sounds and diseases and abnormalities of respiratory function are well established. Correct identification of lung sounds, and consistency in terms used to describe them, therefore permits greater diagnostic accuracy and provides the ability to accurately and precisely describe diseases. The identification and clinical significance of respiratory sounds are summarized in Table 10.1. The clinician must carefully auscultate both the upper respiratory tract (larynx, trachea) and the entire aspects of both lung fields and interpret the sounds that are audible or not audible. The variables that must be interpreted include:

- The nature of the sounds (increased or decreased breath sounds, crackles or wheezes)
- The timing of the sounds in the respiratory cycle

- Their anatomical location.
- The questions that should be asked are:
  - Are breath sounds audible?
  - Are the breath sounds of normal intensity?
  - Are the breath sounds normal or abnormal?
  - If abnormal sounds are present, what are they (crackles, wheezes, stridor, stertor, etc.; see Table 10.1)?
  - Are breath sounds audible over all lung fields?

Interpretation of these variables should indicate the nature of the lesion. Examples are summarized in Table 10.1. Lung sounds can be divided into normal breath sounds and abnormal breath sounds.

Breath sounds are produced by air movement through the tracheobronchial tree. The terms ‘bronchial sounds’ and vesicular sounds are not anatomically accurate or based on physiological principles and should not be used. The term ‘breath sounds’ should be used. These are the sounds which are audible clearly over the trachea and which are attenuated over the lungs. Breath sounds are of normal, increased or decreased intensity. Abnormally loud or soft breath sounds can be attributed to either changes in sound production in the airways by changes in flow rate or altered transmission of sound through various normal or abnormal tissues or fluids in the thorax, as discussed above.

Normal breath sounds

Normal breath sounds vary in quality depending on where the stethoscope is placed over the respiratory tract. They are loudest over the trachea and base of the lung and quietest over the diaphragmatic lobes of the lung. Normal breath sounds are louder on inspiration than on expiration because inspiration is active with more rapid airflow, whereas expiration is passive in normal animals and associated with lower rates of airflow. Breath sounds may be barely audible in obese animals or in the noisy surroundings common in field conditions.

Increased loudness of breath sounds is heard in normal animals with increased respiratory rate and depth of respiration. This can occur for physiological reasons such as exercise, excitement or a high environmental temperature. They can also occur in abnormal states such as fever, acidosis or pulmonary congestion in early pneumonia or myocardial disease.

Decreased loudness or an almost complete absence of breath sounds occurs in pleural effusion or pneumothorax because of almost complete reflection of the breath sounds at the pleural surface due to the mismatching of the
acoustic properties of the pleural tissues and fluids. **Space-occupying masses** between the lung and the thoracic wall also cause a relative absence of breath sounds over the site as do areas of lung that are not ventilated, such as a pulmonary abscess.

**Increased loudness of breath sounds**
The normal breath sounds heard over the trachea may sound abnormally loud over the lungs because of changes in the transmission properties of the respiratory system. This is because, when sound waves pass through structures of different physical properties, the amount of sound transmitted depends on the matching of acoustic properties of the different structures. Consolidation results in less reflection of sound at the thoracic wall and consequently more transmission to the stethoscope. Thus, in consolidation, the breath sounds are much louder than normal. These are harsh breath sounds that approximate those heard over the trachea. They are audible on inspiration and expiration but become louder on expiration in abnormal states such as consolidation or atelectasis. Any disease in which the bronchial lumen remains open and the surrounding lung tissue has been replaced by cells, exudate or tissues (consolidation) that transmit sound without reflection will result in increased bronchial sounds.

**Abnormal breath sounds**
Abnormal breath sounds include **crackles** and **wheezes**. Crackles are discontinuous sounds and wheezes are continuous sounds. Crackles are abnormal lung sounds described as clicking, popping or bubbling sounds audible over the trachea and lungs.

</table>
sounds. They are caused by airways that remain closed for a portion of inspiration and then suddenly open. The crackling is caused by the sudden equalization of pressure between the proximal and distal part of the airway.6 Crackles may thus be caused by the presence of exudate and secretions in the airways, and edematous bronchial mucosa. Crackling lung sounds are also audible in cattle with interstitial pulmonary emphysema. Crackling sounds may move their point of maximum intensity following coughing, presumably as a result of movement of exudate.

Wheeze s are continuous whistling, squeaking sounds caused by vibrations of airways or air passing through a narrowed airway. They can be characterized as monophonic (single tone) or polyphonic (multiple tones) and by the timing of their occurrence in the respiratory cycle. Inspiratory wheezing suggests obstruction of the upper airways, usually extrathoracic. Expiratory wheezing usually indicates intrathoracic airway obstruction such as bronchoconstriction with or without distal airways that are narrowed because of tenacious exudate.

Pleuritic friction sounds are a combination of continuous and discontinuous sounds produced by the rubbing together of inflamed parietal and visceral pleura. The sound is loud, coarse and usually not influenced by coughing. Pleuritic friction sounds are not common and their absence does not preclude the presence of pleuritis, particularly in the horse. Pleuritic friction rubs may also occur in cattle with severe diffuse pulmonary emphysema as the relatively dry parietal and visceral surfaces rub together during the respiratory cycle.

Absence of lung sounds occurs when the breath sounds are reflected at the interface between the lung and thoracic wall by the presence of a medium such as a space-occupying mass, fluid or air. The common causes of the ‘silent lung’ include pleural effusion, space-occupying masses of the thorax, large pulmonary abscesses, complete destruction of a lobe of lung including the terminal airways, such as can occur with bronchial lumen occlusion by a foreign body or tumor, and diaphragmatic hernia.6

Extraneous sounds. Miscellaneous unexpected sounds that are occasionally audible over the thorax include peristaltic sounds, skin and hair sounds caused by the stethoscope, crepitating sounds due to subcutaneous emphysema and muscular contractions. Subcutaneous emphysema occurs in diseases in which there is leakage of air from the lungs or airways into the subcutaneous space. This occurs with bullous lung disease in cattle, rib fractures and pneumothorax, and after percutaneous tracheal aspirate in animals that cough. Coughing in these animals causes air to be forced out of the trachea through the hole through which the tracheal aspirate was obtained. This occurs in the period of coughing when intrathoracic pressures are markedly increased just prior to the opening of the glottis.

RESPIRATORY NOISES

Respiration may be accompanied by audible noises that indicate certain normal or abnormal occurrences in the respiratory tract such as sneezing, snorting, stridor, stertor or snoring, wheezing, roaring, expiratory grunting and snuffling, bubbling and rattling sounds.

Sneezing is a sudden, involuntary, noisy expiration through the nasal cavities caused reflexly by irritation of the nasal mucosa. Sneezing occurs in rhinitis and obstruction of the nasal cavities, and digital manipulation and examination of the nasal mucosa.

Snorting is a forceful expiration of air through the nostrils as in a sneeze, but a snort is a voluntary act used by horses and cattle as a device to intimidate potential predators.

Stridor is an inspiratory stenotic sound originating from a reduction in the caliber of the larynx, as occurs in laryngeal edema and abscess.

Stertor or snoring is a deep guttural sound on inspiration originating from vibrations of pharyngeal mucosa. Snoring is often intermittent, depending on the animal’s posture. For example, a fat young bull will often snore when he is dozing half asleep, with his head hung down, but the snore will disappear when he is alert and his head is held up in a more normal position. Stertor can occur during expiration in horses with dorsal displacement of the soft palate.

Wheeze is a high-pitched sound made by air flowing through a narrow lumen, such as a stenotic or inflamed nasal cavity.

Roaring may occur during exercise and is caused by air passing through a larynx with a reduced lumen, e.g. laryngeal hemiplegia in horses.

Expiratory grunting is a clearly audible grunting noise synchronous with expiration. It is most common in cattle with diffuse pulmonary disease. A painful grunt may occur in painful diseases of the thorax such as fibrinous pleuritis and is unassociated with inspiration or expiration.

Snuffling, bubbling or rattling sounds may be audible over the trachea or base of the lungs when there is an accumulation of secretion, or exudate, in the nasal cavities, larynx or trachea. These are most clearly audible on inspiration.

COUGHING

A cough is an explosive expiration of air from the lungs. It is initiated by reflex stimulation of the cough center in the medulla oblongata by irritation of sensory receptors in one of various organs, especially the respiratory tract. The stimulus may originate in the pharynx, larynx, trachea or bronchi. Coughing may also be initiated by irritation of the esophagus, as in choking. The act of coughing consists of several stages:

- Deep inspiration followed by closure of the arytenoid cartilages (glottis)
- Compression of the air in the lungs and large increase in pressure in the thorax and airways by a forced expiratory effort against a closed glottis
- A sudden relaxation of the arytenoid adductor muscles, resulting in opening of the larynx and abrupt, vigorous and forced expiration. Coughing in horses is associated with transient dorsal displacement of the soft palate so that material in the airways caudal to the larynx is expelled through the mouth
- The sudden opening of the glottis allows an explosive expiration, during which the linear velocity attains a speed of several hundred kilometers per hour. The intrathoracic airways collapse after opening of the glottis during the forced expiration, whereas the extrathoracic airways are momentarily diluted.

The purpose of coughing is to remove the excess mucus, inflammatory products or foreign material from the respiratory tract distal to the larynx. Coughing indicates the existence of primary or secondary respiratory disease. Coughing can be assessed according to several characteristics. Coughing is infrequent in the early stages of respiratory tract disease but can become frequent as the degree of inflammation in the larynx, trachea and bronchi becomes more severe. Assessment of the severity of coughing, at least in horses, requires prolonged observation (preferably for an hour).7 Coughing is a fairly specific but not very sensitive indicator of pulmonary inflammation.8 If coughing is detected then it is quite likely that the animal has inflammation of the airways, whereas failure to detect coughing does not reliably rule out the presence of clinically significant airway inflammation.8 The severity of coughing in horses is closely linked to the severity of inflammation.
and accumulation of mucous in the airways.\textsuperscript{7,8} Race horses that cough are 10 times more likely to have more than 20% neutrophils in a tracheal aspirate, and more than 100 times more likely to have more than 80% neutrophils.\textsuperscript{9} The frequency of coughing correlates well with maximal changes in pleural pressure, extent of mucus accumulation and proportion of neutrophils in bronchoalveolar lavage fluid of horses with heaves (recurrent airway obstruction).\textsuperscript{7} Coughing is therefore a specific indicator of the presence of respiratory inflammation.

The frequency of coughing is an indicator of the severity of lung disease in horses\textsuperscript{7} and presumably in other species. Horses that cough more than four times per hour have increased likelihood of mucus accumulation and higher pleural pressure changes during breathing than do horses that cough fewer than four times per hour.\textsuperscript{7}

A cough cannot be induced in normal adult cattle and horses by manual manipulation of the larynx or trachea. If a cough can be induced in an adult horse by manual manipulation of the larynx or trachea, this indicates airway inflammation and is a reason for further examination of the respiratory tract.

The most common causes of coughing in farm animals are due to diseases of the larynx, trachea, bronchi and lungs, which are presented under the headings of diseases of those parts of the respiratory tract later in this chapter.

**CYANOSIS**

Cyanosis is a bluish discoloration of the skin, conjunctivae and visible mucosae caused by an increase in the absolute amount of reduced hemoglobin in the blood. It can occur only when the hemoglobin concentration of the blood is normal or nearly so, and when there is incomplete oxygenation of the hemoglobin. Cyanosis is apparent when the concentration of deoxygenated hemoglobin in blood is greater than 5 g/dL (50 g/L).\textsuperscript{9} Cyanosis does not occur in anemic animals. The bluish discoloration should disappear when pressure is exerted on the skin or mucosa. In most cases, the oral mucous membranes are examined for evidence of cyanosis, although the skin of the pinna and the urogenital mucous membranes will suffice. Examination of vaginal mucosa is preferred in horses that have severe congestion of the oral and nasal mucosa as a result of disease affecting the head, such as cellulitis or bilateral jugular thrombophlebitis. Artificial lighting and skin pigmentation affect the ability to detect cyanosis.

**Methemoglobinemia** is accompanied by discoloration of the skin and mucosae but the color is more brown than blue and cannot be accurately described as cyanosis.

Cyanosis is classified as central or peripheral. **Central cyanosis** is present when arterial oxygen saturation is below normal with concentration of deoxygenated hemoglobin exceeding 4–5 g/dL. **Peripheral cyanosis** occurs when there is localized desaturation of blood despite arterial oxygen saturation being normal. This usually occurs because there is diminished blood flow to tissue, with a resulting increase in oxygen extraction by the ischemic tissues and low end-capillary and venous hemoglobin saturation.

Central diseases include:

- Congenital cardiac diseases that cause right-to-left shunting
- Pulmonary diseases that cause hypoxemia. Cyanosis is not usually marked in pulmonary disease unless the degree of ventilation/perfusion mismatch is severe
- Upper airway obstruction causing hypoxemia. Cyanosis is common and is a sign of life-threatening disease in severe cases of laryngeal obstruction, as occurs in severe laryngitis in calves with necrotic laryngitis or horses with bilateral laryngeal paralysis (lead poisoning, after tracheal intubation during anesthesia, idiopathic)
- Abnormalities in hemoglobin function.

Peripheral causes of cyanosis include:

- Arterial obstruction, such as is seen in horses with aortoiliac thrombosis ('saddle thrombus') or thrombosis of distal limbs (such as can occur with severe septicemia)\textsuperscript{10}
- Venous obstruction
- Severe vasoconstriction.

**Central cyanosis** is characterized by decreased arterial oxygen saturation due to right-to-left shunting of blood or impaired pulmonary function. Central cyanosis due to congenital heart disease or pulmonary disease characteristically worsens during exercise. Central cyanosis usually becomes apparent at a mean capillary concentration of 4–5 g/dL reduced hemoglobin (or 0.5 g/dL methemoglobin). Since it is the absolute quantity of reduced hemoglobin in the blood that is responsible for cyanosis, the higher the total hemoglobin content the greater the tendency toward cyanosis. Thus cyanosis is detectable in patients with marked polycythemia at higher levels of arterial oxygen saturation than in patients with normal hematocrit values, and cyanosis may be absent in patients with anemia despite marked arterial desaturation. Patients with congenital heart disease often have a history of cyanosis that is intensified during exertion because of the lower saturation of blood returning to the right side of the heart and the augmented right-to-left shunt. The inspiration of pure oxygen (100\% \textsubscript{F}\textsubscript{O2}) will not resolve central cyanosis when a right-to-left shunt is present, but can resolve when primary lung disease or polycythemia is causing the cyanosis.

**Peripheral cyanosis** is caused by obstruction of blood flow to an area. This can occur as a result of arterial or venous obstruction, although it is usually more severe when arterial blood flow is obstructed. Obstruction of arterial blood flow also causes the limb to be cold and muscle and nerve function in the ischemic area to be impaired. Cyanosis can also occur as a result of cutaneous vasoconstriction due to low cardiac output or exposure to cold air or water. It usually indicates stasis of blood flow in the periphery. If peripheral cyanosis is localized to an extremity, arterial or venous obstruction should be suspected. Peripheral cyanosis due to vasoconstriction is usually relieved by warming the affected area.

Heart failure can cause cyanosis that is restricted to the extremities, probably because of reduced blood flow to extremities during this disease and the consequent markedly lower end-capillary oxygen content. Blood in the venous end of the capillaries, and in the venous bed draining these tissues, is therefore deoxygenated and cyanosis is observed. While this type of cyanosis has a peripheral distribution, its underlying cause is central.

**NASAL DISCHARGE**

Excessive or abnormal nasal discharge is usually an indication of respiratory tract disease. Nasal discharges are common in all the farm animal species. Cattle can remove some or all of the nasal discharge by licking with their tongue, while horses do not remove any.

**Origin**

The nasal discharge is usually obvious but the determination of its origin and significance can be difficult and elusive. The history should determine the duration of the nasal discharge and if it has been unilateral or bilateral.

Nasal discharges may originate from lesions in the nasal cavities, congenital defects of the hard palate such as cleft palate in the newborn, paranasal sinuses, guttural pouch in the horse, pharynx, larynx, trachea and lungs. Diseases of the esophagus and stomach that cause dysphagia and regurgitation or vomiting can also cause a nasal discharge stained with feed material.
The origin of a nasal discharge is sometimes determined by close inspection of the external nares and the visible aspects of the nasal cavities using a pointed source of light. Some important infectious diseases of the respiratory tract characterized by lesions of the nasal mucosa can be identified by examination of the external nares for the origin of a nasal discharge. If the source of the discharge is not apparent on this examination, then more detailed investigation is warranted.

**Examination**

The characteristics of the discharge are noted carefully by inspection. It may be copious, serous, mucoid, purulent, caseous, streaked with blood, foul-smelling (ozena) or contain feed particles.

- A copious bilateral serous nasal discharge is characteristic of early inflammation of the nasal cavities such as in viral rhinitis.
- A bilateral mucoid discharge suggests inflammation of a few days duration.
- A bilateral purulent discharge can indicate inflammation in the upper or lower respiratory tract.
- A copious bilateral caseous discharge suggests an allergic or bacterial rhinitis.
- Foul-smelling nasal discharges are usually associated with necrosis of tissues anywhere in the nasal cavities, the guttural pouch in the horse, or severe necrotic and gangrenous pneumonia.
- A bilateral foul-smelling discharge containing feed particles suggests dysphagia, regurgitation or vomition.
- In most cases, a chronic unilateral nasal discharge suggests a lesion of one nasal cavity.
- A bilateral nasal discharge suggests a lesion posterior to the nasal system.

Examination of the paranasal sinuses for evidence of pain and facial deformity will assist in the diagnosis of sinusitis. Percussion is useful in identifying paranasal sinuses that are filled with fluid or tissue as sinuses affected in this way do not produce a resonant sound when the skin overlying the sinus is tapped. The pharynx and larynx of cattle can be examined through the oral cavity whereas the larynx and the trachea, preferably to the level of the carina, although this might not be possible in large animals or when short endoscopes are used.

**Radiography** of the structures of the head and pharynx is also useful to locate lesions of the nasal cavities and paranasal sinuses that might be the origin of a nasal discharge.

**Nasal discharge and location of lesion**

There is not necessarily a correlation between the characteristics of a nasal discharge and the nature of any pulmonary lesions. In exudative pneumonias in cattle, mucopurulent material is produced and is moved up the trachea and into the pharynx by the mucociliary mechanism or by coughing. Some of it is then swallowed and some may be deposited in the nasal cavities and moved forward to the external nares by ciliary action. In the horse, with its long soft palate, most purulent material from the lungs will be deposited in the nasal cavities and appear as a nasal discharge.

**Sampling of nasal discharge**

When infectious disease is suspected, nasal swabs can be collected and submitted for microbiological examination. Nasal swabs are useful only when a specific etiological agent is suspected and demonstration of its presence will confirm the cause of the disease. Examples of this include streptococcal (Streptococcus equi), influenza (equine or porcine), infectious bovine rhinotracheitis and Mycoplasma bovis. Submission of nasal swabs for culture yields mixed flora and the results are impossible to interpret, with the exception noted above. Organisms cultured from nasal or nasopharyngeal swabs are not representative of those cultured from lungs in individual animals but might be somewhat useful in herd outbreaks of disease.**

Esp, Culture of trans-tracheal aspirates or, in cattle but not horses, bronchial lavage fluid, is representative of organisms causing pulmonary disease.**

Cytological examination of the nasal discharge can reveal exfoliated cells in the case of nasal tumors or eosinophils when allergic rhinitis is present.

**EPISTAXIS AND HEMOPTYSIS**

- Epistaxis (blood from the nostril) is in most instances a result of disease of the mucosa of the upper respiratory tract but it may originate anywhere in the upper or lower respiratory tract. Epistaxis occurring during or within several hours of intense exercise by horses is due to exercise-induced pulmonary hemorrhage.
- Hemoptysis is the coughing up of blood. The blood usually originates from hemorrhage in the lower respiratory tract. The presence of hemoptysis is difficult to detect in animals. Hemoptysis occurs in horses, which is perhaps unexpected given the anatomic separation of the nasopharynx and oropharynx.

Pulmonary hemorrhage, particularly in the horse, may be manifested as epistaxis. Pulmonary hemorrhage in cattle is commonly manifested as hemoptysis and epistaxis. These are described in more detail later in this chapter.

A small amount of serosanguineous fluid in the nostrils, as occurs in equine infectious anemia and infectious equine pneumonia, does not represent epistaxis, which must also be differentiated from the passage of blood-stained froth caused by acute pulmonary edema. In this instance the bubbles in the froth are very small in size and passage of the froth is accompanied by severe dyspnea, coughing, and auscultatory evidence of pulmonary edema.

**THORACIC PAIN**

Spontaneous pain, evidenced by grunting with each respiratory cycle, usually indicates pleural pain, such as from a fractured rib, torn intercostal muscle or traumatic injury, including hematomas of the pleura, or pleurisy. A similar grunt may be obtained by deep palpation or gentle thumping over the affected area of the thoracic wall, with a closed fist or a percussion hammer. Pain due to a chronic deep-seated lesion cannot be detected in this way. The use of a pole under the sternum, as described under traumatic reticuloperitonitis, provides a useful alternative.

**Special examination of the respiratory system**

In addition to the routine clinical examination of the respiratory tract, there are a number of diagnostic techniques that can be used to aid in making a specific diagnosis, providing a reliable prognosis and formulating the most rational treatment. These techniques are being used more commonly by species specialists, particularly on valuable animals. Most equine practices have flexible endoscopes for the examination of the upper respiratory tract of horses. Medical imaging using thoracic radiography and ultrasonography of animals with suspected lung disease is now common, and the laboratory evaluation of respiratory tract secretions and exudates are commonplace. All these techniques increase the
costs of making a diagnosis, and it is therefore important to consider whether the additional diagnostic testing will improve the final outcome of the case. Techniques for advanced evaluation of the respiratory system include:

- Auscultation and percussion of the thorax
- Endoscopy of the upper airways, guttural pouch (in Equidae), trachea, bronchi and larger bronchioles
- Invasive endoscopic examination of the sinuses using rigid endoscopes
- Pleuroscopy using either rigid or flexible endoscopes
- Radiographic examination of the skull, pharynx, larynx, guttural pouch (in Equidae), trachea and thorax
- Computed tomographic and magnetic resonance imaging
- Scintigraphic examination of respiratory function
- Ultrasonographic examination of the soft tissue of the pharynx and larynx, and thorax
- Collection and evaluation of respiratory tract secretions:
  - Nasal
  - Paranasal sinus
  - Guttural pouch
  - Pharyngeal
  - Tracheobronchial (tracheal aspirates, bronchoalveolar lavage)
  - Pleural (thoracocentesis)
- Pulmonary function testing, including measurement of tidal and minute volumes, pleural pressure, forced expiratory volume, flow-volume loops, forced oscillometry, and CO₂ breathing
- Arterial blood gas analysis
- Venous blood gas analysis
- Blood lactate concentration
- Pulse oximetry
- Collection and analysis of exhaled breath condensate
- Lung biopsy
- Respiratory sound spectrum analysis
- Exercise testing.

**AUSCULTATION AND PERCUSSION**

The techniques of auscultation and percussion used in examination of the thorax are discussed in Chapter 1 and references on percussion of the thorax are available. Percussion of the thorax is a useful means of determining lung margins and therefore of detecting the presence of overinflation, as occurs with heaves in horses, or areas of consolidation. Consolidation is evident as a loss of resonance, and detection of this abnormality can reveal the presence of excessive pleural fluid or pulmonary consolidation. There is excellent agreement in the assessment of lung margins determined by percussion and by ultrasonographic examination. Perfusion is therefore a valuable diagnostic tool, especially when ultrasonographic examination is not available.

**ENDOSCOPIC EXAMINATION OF THE AIRWAYS (RHINOLARYNGOSCOPY, TRACHEOBRONCHOSCOPY)**

**Horses**

Flexible endoscopes allow examination of the upper respiratory tract of horses including the nasal cavities, nasopharynx, auditory tube diverticulum (guttural pouches), palatal arch, epiglottis, larynx, trachea and major bronchi. For examination to the level of the rostral trachea an endoscope of 1 m in length is suitable. However, an endoscope of 1.5 m in length is useful for examining to the level of the thoracic inlet. The endoscope is usually less than 1.5 cm in diameter. Endoscopic examinations are tolerated by most horses with the minimum of restraint (application of a nose or ear twitch). Sedation should be avoided if a purpose of the examination is to determine the functional integrity of the pharynx and larynx. Sedation depresses laryngeal function and impairs assessment of the symmetry and abductor function of the arytenoid cartilages. Sedated horses are more likely to displace the soft palate and to fail to return it to its normal position.

**Rhinolaryngoscopy** examination of horses should include a careful examination of the ventral and middle meatuses, turbinates, region of the nasomaxillary sinus opening (this cannot be visualized directly but discharge from it can be detected), ethmoidal turbinates, nasopharynx, soft palate, guttural pouches, dorsal pharyngeal recess, epiglottis and larynx. The endoscope should be used to examine both left and right nasal cavities and ethmoid turbinates. Both guttural pouches should be examined. Passage of the endoscope into the guttural pouch is best achieved by passing the endoscope through the ipsilateral nasal cavity. The guttural pouch is then entered by first introducing a thin, stiff tube, such as an endoscopic biopsy instrument, through the biopsy port of the endoscope into the guttural pouch. The endoscope is then rotated so that the entrance to the guttural pouch is opened and the endoscope is carefully advanced into the pouch. An alternative technique involves insertion of a stiff catheter, such as a Chambers mare uterine catheter, into the guttural pouch such that the entrance is dilated to enable passage of the endoscope.

Many disorders of the equine pharynx and larynx manifest only during strenuous exercise because of the high pressures generated in the airways by the large minute ventilation of exercising horses. Pressures in the pharynx and larynx that are of similar magnitude to those occurring during intense exercise can be induced in resting horses by 60 seconds of nasal occlusion. The respiratory efforts of horses during nasal occlusion can therefore be used to simulate those during exercise, thereby permitting detection of disorders of the pharynx (displacement of the soft palate) and larynx (mild laryngeal hemiplegia) that would not otherwise be apparent in a resting horse. Rhinolaryngoscopic examination can also be performed on horses running on a treadmill (see Exercise testing, below).

**Bronchoscopic examination** requires an endoscope that is at least 2 m in length and less than 1.5 cm in diameter. Horses must be sedated for bronchoscopic examination (a combination of xylazine, 0.25–0.5 mg/kg intravenously, and butorphanol, 1 mg per 40 kg intravenously, works well). Instillation of lidocaine (20 mL of 2% lidocaine diluted with 40 mL of isotonic saline or similar) minimizes coughing. The lidocaine is instilled into the trachea through the biopsy channel of the endoscope. The airways are examined in a systematic fashion and results are recorded using a system that has been described for identifying the major airways. Lobar bronchi are identified on the basis of the side of the bronchial tree on which they are found and the order in which they originate from the primary bronchus. On the right side, R1, R2, and R3 refer to the right cranial lobar bronchi and subsequent right bronchi, respectively. On the left side, L1 and L2 refer to the left cranial lobar bronchi and the left caudal lobar bronchi, respectively. Segmental bronchi are identified by consecutive numbers in the order of origin from the lobar bronchi. The direction of the segmental bronchus is denoted by the capital letters D (dorsal), V (ventral), L (lateral), M (medial), R (rostral) and C (caudal). Subsegmental bronchi are identified in the order of origin from the segmental bronchi, using lower case letters.

**Cattle**

The nasopharynx, pharynx and larynx of cattle can be examined by endoscopy and this should be done without sedation if possible. Xylazine is not recommended because it commonly interferes with normal laryngeal function. Acepromazine is recommended if necessary.

The anatomy of the proximal portion of the respiratory tract of cattle differs from that of horses. The nasal septum does not completely separate the left and
right aspects of the nasopharynx. In cattle, the nasal septum tapers caudodorsally, allowing both ethmoturbinals to be observed from one side. The pharyngeal septum is contiguous with the nasal septum and merges with the caudodorsal wall of the pharynx. The nasopharyngeal openings of the auditory tubes are visible. The appearance of the vocal cords is similar to that observed in the horse. Cattle do not have a laryngeal saccul and a laryngeal vestibule is not visible rostral to the vocal cords. During endoscopy, the arytenoid cartilages are maintained in fully abducted position. Constriction of the pharynx during swallowing is accompanied by rostroventral movement of the pharyngeal septum, completely occluding the nasopharynx, which differs from the situation in the horse.

**ENDOSCOPY OF PARANASAL SINUSES**

The paranasal sinuses of the mature horse can be examined with a 4 mm arthroscope while standing and sedated or under general anesthesia. The procedure is technically challenging and is usually performed by surgeons experienced in the use of arthroscopic equipment inserted through portals created by trephining holes in the sinus. The side to be examined is determined by physical, radiographic and rhinoscopic examination of the animal. Endoscopic examination is indicated in animals in which diagnosis of the disease requires collection of tissue from the sinus. Therapeutic interventions that can be performed during endoscopic examination of the paranasal sinuses include lavage, removal of accretions of inflammatory material, drainage of cysts and creation or enlargement of drainage holes.

**PLEUROSCOPY**

Pleuroscopy using a rigid or flexible endoscope enables direct visual inspection of the pleural cavity for the diagnosis of pleural disease. The technique is particularly valuable in diagnosis of diseases of the thorax that extend to the pleural surface and do not exfoliate large quantities of cells, thereby making diagnosis by examination of fluid obtained by pleurocentesis unlikely. The procedure is useful in collection of tissue samples, such as from suspected thoracic neoplasia, or in therapeutic procedures including relief of pleural adhesions and resection of lung sections. The procedure is performed in standing, sedated horses restrained in stocks. Strict aseptic technique is used. The portal for insertion of the endoscope is at the level of the eighth to 12th intercostal space with optimal examination of intrathoracic structures obtained via the 10th or 12th intercostal space. Either a rigid endoscope (10 mm diameter, 57 cm length) or flexible endoscope (10 mm diameter, 1 m length) can be used. The endoscope is inserted through a small incision in the intercostal space made under local anesthesia. The ipsilateral lung is partially collapsed by induced pneumothorax to permit visualization of intrathoracic structures. The mediastinum is intact in most horses. Inadequate collapse of the lung increases the likelihood of it being damaged during the procedure. The lung is reinfal by removal of air in the pleural space at the end of the procedure. Potential complications of the procedure include pneumothorax, hemothorax, damage to intrathoracic structures and infection.

**RADIOGRAPHY**

Radiography of the head, neck and thorax is valuable in the diagnosis of diseases of the respiratory tract of animals. Examination is hindered by the large size of adult horses and cattle through the need for specialized, high-capacity equipment for obtaining radiographs, and the need for adequate restraint. Radiographic examination of adult animals in the field using portable radiographic units is limited. However, large practices with fixed radiographic units capable of generating sufficient voltage and amperage can obtain diagnostic radiographs of the thorax of adult horses and cattle. Diagnostic films of smaller animals, including adult sheep and goats and foals and calves, can be obtained using portable units capable of generating 80–100 kVp and 15–20 mA.

Examination of the thorax of large animals is restricted to lateral radiographs because the large amount of tissue prevents adequate exposure for ventrodorsal views. Multiple films are required for complete examination of the thorax, and the exposure needed for optimal quality films varies among anatomical sites. Localization of focal lesions can be achieved by examining sets of radiographs that include images collected with the horse or cow standing first with one side to the plate and then with the other side toward the plate. The lesion will appear larger in views obtained with the lesion closer to the source of X-rays.

Radiographs of *calves and foals* can be recorded with them standing or recumbent. Images obtained with the calf or foal in lateral recumbency with the forelimbs pulled forward permit optimal examination of the cranial thorax. However, calves or foals that are recumbent for prolonged periods of time (e.g., >30 min) can develop atelectasis of the down lung that can mimic pneumonia radiographically. Ventrodorsal views assist with localizing lesions in foals and calves. Radiographic evidence of lung disease is common in ill neonatal foals (74% having such lesions in one study), and is not related to clinical evidence of respiratory disease or dyspnea. The characteristics of lung lesions detected in neonatal foals are associated with likelihood of survival. Guidelines for recognition of pulmonary patterns in foals have been proposed (Table 10.2) and these guidelines are likely to be useful aids for interpretation and description of pulmonary patterns in neonates of other species.

Radiography can assist in the recognition and differentiation of atelectasis and consolidation, interstitial and exudative pneumonias, the alveolar pattern of pulmonary disease, neoplasms, pleural effusions, pneumothorax, hydropericardium and space-occupying lesions of the thorax. Cardiomegaly, abnormalities of the cranial mediastinum, fractures of ribs and diaphragmatic hernia can also be detected.

Many pulmonary diseases do not have lesions that are readily detected on radiographic examination. Failure to detect abnormalities on radiographic examination of the thorax does not eliminate pulmonary disease. Furthermore, radiographically detectable signs of lung disease can persist after the animal has clinical and clinicopathological signs of recovery or improvement.

**Bronchography** utilizing contrast agents is of value in determining the patency of the trachea and bronchi, but general anesthesia is required to overcome the coughing stimulated by the passage of the tracheal catheter. Using a fluoroscope to determine the location of the catheter tip, the contrast agent can be deposited in each dependent lobe in turn. This technique is used infrequently.

Computed tomographic (CT) examination of the lung is very sensitive and specific for lung disease in companion animals and is technically feasible in calves, foals and small ruminants. The technique is useful in the diagnosis of mediastinal disease in foals.

Radiographic examination of the trachea can reveal the presence of abnormalities in shape, such as occur with tracheal collapse, or the presence of foreign bodies or exudate.

Radiographic examination of the head can identify diseases of the paranasal sinuses, ethmoids and pharynx. Radiographic examination is useful in defining diseases of the guttural pouches and in detecting retropharyngeal abscesses or abnormalities, such as the presence of foreign bodies. The CT anatomy of the head of horses and foals has been
CT imaging of the nasal cavities and paranasal sinuses of horses is useful in the detection of diseases of these structures, and of the teeth, pharynx, larynx and guttural pouches. The technique is technically feasible in ruminants described. CT imaging of the nasal cavities and paranasal sinuses of horses is useful in the detection of diseases of these structures.

**Table 10.2: Guidelines For Radiographic Pulmonary Patterns (Comprised in Pairs)**

<table>
<thead>
<tr>
<th>Alveolar lung pattern (Vessels not visualized. There is displacement of air from the distal air spaces of the lung leading to a relatively homogeneous increase in soft tissue opacity. Formation of air bronchograms is usually associated with the pattern but is not always present)</th>
<th>Absent</th>
<th>The pulmonary vessels are easily seen</th>
</tr>
</thead>
<tbody>
<tr>
<td>Minimal alveolar component (&lt; 10%)</td>
<td>No visualization of vessels in &lt; 10% of the lung field. Usually occurs in conjunction with a moderate or severe interstitial lung pattern</td>
<td></td>
</tr>
<tr>
<td>Focal (&gt; 10% to 30%)</td>
<td>No visualization of vessels in 11–30% of lung fields. Air bronchograms might or might not be present within &lt; 30% of lung fields</td>
<td></td>
</tr>
<tr>
<td>Localized (&gt; 30% to 50%)</td>
<td>No visualization of vessels in 31–50% of lung fields. Air bronchograms might or might not be present within &lt; 50% of lung fields</td>
<td></td>
</tr>
<tr>
<td>Extensive (≥ 50%)</td>
<td>No visualization of vessels in ≥ 50% of lung fields. Air bronchograms might or might not be present throughout the entire section of lung field</td>
<td></td>
</tr>
</tbody>
</table>

**Interstitial lung pattern (Characterization of the non-air-containing elements of the lungs including blood vessels and bronchi)**

<table>
<thead>
<tr>
<th>Normal</th>
<th>Clear visualization of vessels. Borders are well defined</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mild increase</td>
<td>The pulmonary vessels appear slightly ill defined (hazy borders with loss of visualization of the fine vascular structures). Mildly lacy appearance to lung field</td>
</tr>
<tr>
<td>Moderate increase</td>
<td>The vessels are ill defined, resulting in moderately lacy appearance and increased opacity of the lung field</td>
</tr>
<tr>
<td>Marked increase</td>
<td>Significantly increased opacity; vessel borders are barely recognizable</td>
</tr>
</tbody>
</table>

**Bronchial pattern (Characterized by alterations in bronchial wall thickness and density, or in bronchial lumen diameter. Note that peribronchial cuffing is a feature of interstitial but not bronchial pattern)**

<table>
<thead>
<tr>
<th>Normal</th>
<th>Bronchial structures seen in cross section appear as small, thin-walled hollow rings between paired vessels. The bronchial walls are barely distinguishable when viewed side-on and are not clearly visualized at the periphery of the lung field</th>
</tr>
</thead>
<tbody>
<tr>
<td>Moderate increase</td>
<td>A few thickened bronchial walls evident in cross section (‘donuts’) at the periphery of the lung fields. Longitudinal sections appear as tram lines reaching two-thirds of the way to the lung periphery</td>
</tr>
<tr>
<td>Marked increase</td>
<td>Extensive bronchial thickening might be observed, extending far into the periphery of the visible lung field</td>
</tr>
</tbody>
</table>

Magnetic resonance (MR) imaging is useful in diagnosis of diseases of the head, and the anatomy as visualized on MR imaging of the head of horses has been reported. Unfortunately, the lack of units suitable for examination of large animals precludes routine use of this imaging modality.

**SCINTIGRAPHY (NUCLEAR IMAGING)**

The basis of pulmonary scintigraphy is detection at the body surface of radiation emitted from the lungs after injection or inhalation of radioactive substances. The technique has been described in both horses and calves. The technique has limited diagnostic usefulness in large animals because of the need for availability of appropriate isotopes and detection equipment. Furthermore, the large size of adult cattle and horses limits the sensitivity of the technique. The technique has been used to determine the distribution of pharmaceuticals administered by aerosolization and the presence of ventilation/perfusion mismatches. Alveolar clearance can be detected using scintigraphic examination. Currently pulmonary scintigraphy is largely a research tool.

**ULTRASONOGRAPHY**

Ultrasonographic examination of the thorax of farm animals and horses is a very useful diagnostic tool. Ultrasonographic examination of the thorax provides diagnostic information that is not obtained by radiographic examination. The widespread availability of portable ultrasound units and the ability to image parts of the thorax using ultrasound probes intended for examination of the reproductive tract of mares and cows makes this a potentially valuable diagnostic aid for both field and hospital-based practitioners. Furthermore, the absence of radiation exposure and the ‘real-time’ nature of images obtained by ultrasonography aid in frequent assessment and monitoring of abnormalities and performance of diagnostic or therapeutic procedures such as thoracocentesis or aspiration of masses.

There are limitations to imaging imposed by aerated lung and the bones of the rib cage. Examination of the thorax is limited by the presence of ribs and aerated lungs because the sound waves used to create ultrasound images are reflected from these surfaces. Ultrasonography cannot reveal lesions of the lungs that are not confluent with the visceral pleura. Imaging windows are restricted to the intercostal spaces but this impediment can be overcome by scanning through adjacent intercostal spaces and angling of the ultrasound beam.

Ultrasonographic examination of the thorax should be performed in a consistent manner that ensures thorough examination of the thorax. Preferences for the pattern of examination differ somewhat among examiners, but one common and successful technique is to scan each intercostal space from dorsal to ventral starting at the 17th intercostal space in horses and the 12th intercostal space in cattle. The ultrasound probe is slowly moved from dorsal to ventral while the examiner studies the images. When one scanning of one intercostal space is completed, the probe is moved to the most dorsal aspect of the next intercostal space and the examination is repeated. Each side of the chest is examined in this manner. This consistent and thorough examination ensures that no important or localized abnormalities are missed. The examination is performed in adult horses and cattle with the animal standing. The rostral thorax is scanned by pulling the ipsilateral forelimb forward. This is more readily achieved in horses than in cattle. Thorough examination of the rostral thorax might require placing the animal in lateral recumbency. Calves and foals can be examined either standing or in lateral recumbency.

Ultrasonound examination of the thorax is particularly useful for detecting diseases of the pleura, pleural space or lung surface. This is in addition to the well-documented utility of ultrasonographic examination of the heart and great vessels (see Ch. 8). The normal ultrasonographic anatomy of the thorax of cattle, horses and calves has been determined. The following is a partial list of disorders or abnormalities detectable by percutaneous ultrasonographic examination of the thorax of farm animals or horses (excluding cardiac abnormalities):
- Excess pleural fluid
- Characteristics of pleural fluid (floculent, bubbles, fibrin)
- Extent of pleural fluid accumulation
- Localized areas of pleural fluid accumulation
- Nonaerated lung (atelectatic, consolidated)
- Pulmonary abscesses (must be confluent with visceral pleura)
- Intrathoracic masses (thymic lymphoma, cranial thoracic mass, gastric squamous cell carcinoma)
- Pleural roughening (‘comet-tail’ lesions)
- Pneumothorax
- Pulmonary hematoma
- Exercise-induced pulmonary hemorrhage
- Hemorrhax
- Diaphragmatic hernia
- Fractured ribs (especially in neonates).

Ultrasonographic examination is more sensitive and specific than radiographic examination in detecting the presence of pleural fluid and is particularly useful in the diagnosis and management of pleuritis. Ultrasonography can identify pulmonary lesions that are not visible radiographically, including lesions in horses with infectious viral pneumonia. Ultrasonography is easily passed through the nasal cavities and can be unsatisfactory because micro-organisms are anesthetized with local anesthetic. A stab incision (< 1 cm) is made in the skin and subcutaneous tissues. A hole is then drilled into the sinus using a Jacob’s chuck with a length of the Steinmann pin (2–4 mm diameter). Only a short (5 mm) length of the Steinmann pin should be exposed by the chuck. The hole is drilled by applying steady pressure and making alternating clockwise and counterclockwise movements with the chuck. The pin should be exposed by the chuck. Entry into the sinus cavity is evident as a sudden release of tension and easy passage of the Steinmann pin. The pin is then withdrawn and sterile polyethylene tubing is inserted into the sinus cavity. Fluid can be aspirated at this time or, if none is forthcoming, 10–20 mL of sterile 0.9% saline or similar fluid can be instilled to the sinus cavity. Some of this fluid may run out the nostril if the animal’s muzzle is lower than the sinus. Complications include injury to adjacent structures, including the infraorbital nerve (trigeminal nerve), nasolacrimal duct or parotid salivary duct near its entrance to the guttural pouches of equids include:

- Nasopharyngeal swabs
- Nasal lavage
- Tracheal aspiration
- Bronchoalveolar lavage
- Thoracocentesis.

LABORATORY EVALUATION OF RESPIRATORY SECRETIONS

SAMPLING RESPIRATORY SECRETIONS

When an inflammatory disease process of the respiratory tract is suspected, the collection of samples of secretions and exudate for microbiological and cyto- logical examination can be considered. The objective is to obtain a sample uncontaminated with environmental flora, which are common in the upper respiratory tract, and to isolate the pathogen(s) or demonstrate inflammatory cells which may be associated with the lesion. This can be done by:

- Swabbing the nasal cavities or the pharynx
- Collection of fluid from the paranasal sinus
- Collection of fluid from the guttural pouch of Equidae

Nasal Swab

A swab of the nasal cavities is a reliable method for the evaluation of the secretions associated with disease of the upper respiratory tract such as infectious bovine rhinotracheitis and allergic rhinitis. However, when attempting to assess the health status of the lungs the nasal swab can be unsatisfactory because microbi- ological examination usually yields a large population of mixed flora, consisting of pathogens and non-pathogens, which is difficult to interpret.

Nasopharyngeal Swabs

For more reliable results and to lessen the contamination that occurs with nasal cavity samples, swabs of the laryngeal–pharyngeal area can be collected. A swab in a long covered sheath, of the type used for collecting cervical swabs from mares, is easily passed through the nasal cavities to the pharyngeal area. Significant differences may exist between the microbial isolates from nasopharyngeal swabs and those from lung tissues, which makes nasal swabs unreliable for diagnosis. For example, at the individual animal level, nasopharyngeal swabs and bronchoalveolar lavage show only moderate agreement; at the group or herd level the isolation rates of various organisms are similar.

For isolation of viruses associated with disease of the upper respiratory tract, nasal swabs are satisfactory provided a copious amount of nasal discharge is collected and the swabs are kept moist during transport to the laboratory. Nasal swabs sometimes contain an insufficient amount of secretion, and certain viral pathogens can become inactivated in transit.

Nasal Lavage

When larger quantities of nasal discharge are required for research purposes, nasal washings are usually collected, the simplest technique being irrigation of the nasal cavities and collection into an open dish. From these samples, it is possible to isolate bacteria and viruses, and identify immunoglobulins. The development of immunofluorescent and enzyme-linked immunosorbent assay (ELISA) tests for agents of infectious disease has provided reliable systems for the diagnosis of a variety of virus diseases in the early stages of infection. A technique and apparatus are available that obtain much better samples than the conventional cotton-wool swab provides. A vacuum pump aspirates epithelial cells and secretion from the nasal passage and pharynx. Cell smears are then prepared for microscopic examination and the mucus and cells are used for conventional microbiological isolation.

PARANASAL SINUS FLUID

Fluid can be collected from the frontal and paranasal sinuses of most of the domestic large animals. Indications for collection of fluid include the presence or suspected presence of disease of the paranasal sinuses. Medications can be administered and infected sinuses lavaged using this approach. Absolute contraindications are few but include failure to be able to adequately restrain the animal. Demonstration of fluid in the paranasal sinuses is aided by radiographic examination of the skull. Fluid is collected by percutaneous centesis of the frontal or maxillary sinus and submitted for cytological and bacteriological examination (Gram stain, culture). The procedure is restraint of the animal, which can include the induction of moderate sedation by administration of alpha-2 agonists and narcotics, or in cattle restraint in a head gate with the head secured with a halter. The area over the centesis site is prepared aseptically and the skin and subcutaneous tissues are anesthetized with a local anesthetic.

The hole is then drilled into the sinus using a Jacob’s chuck with a Steinmann pin (2–4 mm diameter). Only a short (5 mm) length of the Steinmann pin should be exposed by the chuck. The hole is drilled by applying steady pressure and making alternating clockwise and counterclockwise movements with the chuck. Entry into the sinus cavity is evident as a sudden release of tension and easy passage of the Steinmann pin. The pin is then withdrawn and sterile polyethylene tubing is inserted into the sinus cavity. Fluid can be aspirated at this time or, if none is forthcoming, 10–20 mL of sterile 0.9% saline or similar fluid can be instilled to the sinus cavity. Some of this fluid may run out the nostril if the animal’s muzzle is lower than the sinus. Complications include injury to adjacent structures, including the infraorbital nerve (trigeminal nerve), nasolacrimal duct or parotid salivary duct near its entrance to the oral cavity at the level of the upper cheek teeth. Hemorrhage is usually minor and self-limiting. Subcutaneous emphysema resolves within days. Cellulitis is a risk, especially for animals with septic processes in the paranasal sinuses.

Prophylactic administration of antibiotics should be considered in these cases.

GUTTURAL POUCH FLUID

Indications for collection of fluid from the guttural pouches of equids include
bacteriological or polymerase chain reaction (PCR) examination to determine if the horse is infected by *S. equi* (the etiological agent of strangles) or to investigate the suspected presence of other inflammatory or neoplastic disease. The preferred method of collection is during endoscopic examination of the guttural pouch. During this examination, fluid can be collected through a polyethylene tube inserted through the biopsy port of the endoscope. Fluid collected in this manner is potentially contaminated by organisms in the upper respiratory tract, and results of bacteriological examination should be interpreted with caution. Usually, bacteriological examination is for the presence of *S. equi* and demonstration of its presence is all that is required for a diagnosis of infection. Fluid can also be obtained from the guttural pouch by blunt passage of a firm catheter, such as a Chambers mare catheter or 10 French dog urinary catheter, into the guttural pouch. This procedure requires some skill and there is always the uncertainty that one might not have actually manipulated the catheter into the guttural pouch. A third technique involves percutaneous puncture of the guttural pouch just posterior to the ramus of the mandible and ventral to the ear. This technique has the potential to yield fluid that is uncontaminated by organisms from the upper respiratory tract, but carries with it a high risk of injury to the important vascular and neural structures in and around the guttural pouch (internal and external carotid arteries, pharyngeal branch of the vagus nerve, hypoglossal nerve, and others). Percutaneous sampling of guttural pouch fluid should not be undertaken without careful consideration of the risks and benefits of the procedure.

**TRACHEOBRONCHIAL SECRETIONS**

The collection and evaluation of tracheobronchial secretions is a useful method for assessing lower airway disease and is widely used in the determination of the etiology of infectious pneumonia (viral, mycoplasmal, fungal, and parasitic) or the severity of disease (bronchoalveolar lavage fluid cytology in horses with heaves, exercise-induced pulmonary hemorrhage in athletic horses). It is also used as a tool in evaluating respiratory health of intensively housed animals, such as in piggeries.\(^{35}\) Cytological examination of recovered fluid can provide valuable information about the severity, extent and etiology of disease of the lower airway. There are two methods of sampling tracheobronchial secretions – aspiration of tracheal fluid or lavage of bronchioles and distal airways. Each sampling method yields fluid of differing characteristics and source and interpretation of the results of examination of these fluids depends on their source and the method of collection.

**Comparison of tracheal aspirates and bronchoalveolar lavage fluid**

Examination of tracheal aspirates and bronchoalveolar lavage fluid yields different, but often complementary, information about the lower respiratory tract. The differences between tracheal aspirates and bronchoalveolar lavage fluid arise because cell populations, and types of cell, differ markedly among segments of airways. There is no correlation between cytological features of tracheal aspirates and bronchoalveolar lavage fluid of horses, and this is probably the case in other species.\(^{34}\) Tracheal aspirates are representative of cell and bacterial populations of the large conducting airways (trachea and mainstem bronchi), which can originate in both the large and small conducting airways and the alveoli.\(^{34}\) Secretions of more distal airways can be modified during rostrad movement, such that fluid in a tracheal aspirate is not representative of processes deeper within the lung. Furthermore, disease localized to one region of the lung can alter tracheal fluid. Examination of tracheal aspirates is useful for detecting inflammation of the large airways and for isolation of microorganisms causing disease in these structures. There is no good evidence that findings on examination of tracheal aspirates correlate with abnormalities in pulmonary function, and tracheal aspirates do not accurately reflect lesions in the lungs of horses.\(^{35}\)

Bronchoalveolar lavage is useful for sampling secretions in the more distal airways. It provides a sample of secretions that have not been contaminated by upper respiratory tract organisms or secretions before collection and the sample is therefore assumed to be more representative of small airway and, to a lesser extent, pulmonary parenchymal and alveolar secretions or exudates. Bronchoalveolar lavage fluid is useful in the detection of widespread lung disease but not necessarily in the detection of localized disease. Tracheal aspirates, because they in theory represent a composite sample of secretions from all regions of the lung, are likely to be more sensitive in detecting focal disease, such as a pulmonary abscess. Bronchoalveolar lavage fluid composition correlates well with pulmonary function in horses.\(^{36,37}\)

There is little agreement in cytological examination of tracheal aspirates and bronchoalveolar lavage fluid of sick and healthy horses, and this difference probably exists in other species. Typically, the proportion of cells that are neutrophils is much higher in tracheal aspirates than in bronchoalveolar lavage fluid of both horses with heaves and normal horses.\(^{34,38}\) Mast cells are detected more frequently, and eosinophils less frequently, in bronchoalveolar lavage fluid than in tracheal fluid of normal horses.\(^{39}\)

**Tracheal aspirates**

Indications for collection of tracheal aspirates include the need for microbiological and cytological assessment of tracheal fluids. The primary indication is collection of samples for microbiological diagnosis of infectious respiratory disease. Other indications include detection and characterization of inflammation of the conducting airways. Contraindications include severe respiratory distress, although this is not an absolute contraindication, inability to adequately restrain the animal, and severe, spontaneous coughing. Percutaneous tracheal aspirate collection performed in animals with severe coughing can result in development of severe subcutaneous emphysema as a result of the high intratracheal pressures associated with the early phase of coughing. Most animals in which percutaneous tracheal aspirates are collected subsequently have radiographic evidence of pneumomediastinum.

Tracheal aspirates can be collected either by percutaneous puncture of the trachea or through an endoscope passed through the upper airways. The advantage of percutaneous collection of tracheal aspirates is that there is minimal risk of contamination of the sample by upper respiratory tract or oropharyngeal secretions. Microbiological examination of the samples is therefore likely to accurately reflect microbes present in tracheal fluid. Collection of tracheal aspirates through an endoscope markedly increases the risk of contamination of the sample with oropharyngeal fluids, and compromises the diagnostic utility of culture of the sample. This disadvantage is partially alleviated by the use of guarded catheters inserted through the endoscope.\(^{60,61}\) The disadvantage of percutaneous collection of tracheal fluid is that it is invasive and there is a risk of localized cellulitis and emphysema at the site of puncture. Endoscopic collection is relatively non-invasive and readily accomplished.\(^{5}\) We prefer use of the percutaneous method when accurate microbiological assessment of samples is desired.

**Percutaneous transtracheal aspiration**

This is a practical method that has been used extensively in the horse\(^{60}\) and is adaptable to cattle,\(^{52}\) sheep and goats. For the horse, a 60 cm no. 240–280 polyethylene tube is passed through a 9–14-gauge...
needle or cannula. The skin site is prepared after the area has been anesthetized. The cannula is removed to avoid cutting the tube and the tube is pushed in as far as the thoracic inlet. Fluid typically pools in the trachea at the thoracic inlet in horses with lung disease (the tracheal lake or pool) and it is this fluid that is aspirated. Thirty to 50 mL of sterile saline (not bacteriostatic saline) is rapidly infused. The catheter or tubing should be rotated until tension is felt on aspiration by a syringe. Fluid is aspirated and submitted for cytological, microbiological or other examination.

Complications such as subcutaneous emphysema, pneumomediastinum and cellulitis can occur, which necessitates care and asepsis during the procedure. Sudden movement of the cannula during insertion of the tubing may cause part of the tube to be cut off and to fall into the bronchi, but without exception this is immediately coughed up through the nose or mouth.

Endoscopic sampling of tracheal secretions
The flexible fiberoptic endoscope can be used to obtain tracheal lavage samples and at the same time visualize the state of the airways. The process is as for rhinolaryngoscopic examination with the addition of passage of a catheter through the biopsy port of the endoscope. Tracheal fluid is then visualized and aspirated through the catheter. The clinical advantages of the endoscopic collection include noninvasiveness, visual inspection of the airways, guidance of the catheter, and speed. The use of an endoscope with a guarded tracheal swab minimizes contamination by oropharyngeal secretions but does not eliminate it.

Assessment of results
Microbiological examination can yield any one or more of a variety of bacteria, depending on the species examined, the animal’s age and its clinical condition. Tracheal aspirates of normal animals rarely yield any bacterial growth on culture. Growth of unusual organisms or known oropharyngeal commensal bacteria from samples obtained by endoscopic examination should not be given undue clinical significance as they probably result from contamination of the tracheal aspirate during collection. Pseudomonas spp. and anaerobes isolated from tracheal aspirates collected by endoscopy are almost always contaminants and of no clinical significance. The extent of contamination of tracheal aspirate samples by oropharyngeal bacteria can be estimated from the number of squamous epithelial cells in the sample. There is an apparent approximate linear relationship between the number of squamous cells per milliliter of fluid and the number of colony-forming bacterial units in tracheal aspirates. Samples containing over approximately 10 squamous epithelial cells per milliliter of tracheal aspirate had markedly greater bacterial contamination. Examination of Gram-stained smears of tracheal fluid is specific but not very sensitive for detection of bacteria, compared with culture. In other words, if examination of a Gram-stained smear of tracheal fluid reveals bacteria, then the sample is likely to yield bacteria on culture, whereas failure to detect bacteria predicts poorly the likelihood of growth of bacteria on culture of the sample. This indicates that examination of Gram-stained samples of tracheal fluid does not reliably predict bacterial isolation, and if an infectious etiology is suspected the fluid should be cultured. Results of the microbiological examination of the tracheal fluid should be consistent with the animal’s clinical condition and expected isolates.

Cytological examination of tracheal fluid is an important diagnostic tool. Various stains are available to aid identification of cell types and numbers in tracheal aspirates. Neutrophils, macrophages, lymphocytes and epithelial cells are readily identified on the basis of their classical morphology and staining using fast Romanowsky stain (Diff-Quik®), but this stain is not suitable for identifying mast cells in equine tracheal fluid and probably that of other species. Leishman’s stain is useful to identify mast cells. Leishman’s stain is useful to identify mast cells. Clinically normal horses typically have fewer than 20–30% of cells as neutrophils with the majority of remaining cells being macrophages, lymphocytes and epithelial cells. Animals with inflammation of the Airways typically have increased cell counts and proportion of neutrophils, and large amounts of mucus. Horses with inflammatory disease have typically have more than 20% of the cells as neutrophils (see Heaves, below), and those with infectious pneumonia often have 50–90% of cells as neutrophils. The presence of eosinophils is considered abnormal and is consistent with parasite migration (Parascaris equorum in foals, Dictyocaulus viviparus in calves). The presence of hemosiderin-laden macrophages is evidence of prior pulmonary hemorrhage.

Bronchoalveolar lavage
Bronchoalveolar lavage provides a sample of secretions and cells of the alveolar airways and alveoli, referred to as bronchoalveolar lavage fluid. It is a widely used procedure in horses and, to a lesser extent, cattle and calves, sheep, and pigs. Analysis performed on bronchoalveolar lavage fluid include measurement of cell number and type, culture (usually in pigs and cattle) and analysis of immune proteins and surfactant. It is a relatively noninvasive procedure that allows cytological and biochemical evaluations of the lower airways and alveoli, which are useful diagnostic aids when evaluating animals with lung disease. While fiberoptic bronchoscopy and tracheal aspirates permit assessment of the major bronchi and upper airways, bronchoalveolar lavage offers an extension of the diagnostic potential by sampling the terminal airways and alveolar spaces.

The primary indication for collection of bronchoalveolar lavage fluid is acute or chronic lung disease. This includes both infectious and noninfectious diseases, although interpretation of samples collected by passage of the collection tube through the nostrils or mouth is complicated by the inevitable contamination of the sample by oropharyngeal commensal bacteria. Despite this shortcoming, the technique has been used to detect pneumonia associated with Mycoplasma sp. in cattle. Contraindications are few, with respiratory distress being an obvious one. Complications of bronchoalveolar lavage are also few, and include a mild neutrophilia in lavaged sections of lungs and changes in phagocytic function of pulmonary macrophages, and microbial content for several days after the procedure.

A shortcoming of bronchoalveolar lavage is that it lavages only a small region of the lung, with the risk that focal lung disease is not detected. This is best exemplified in pneumonia in horses, in which bronchoalveolar lavage fluid from pneumatic horses can contain large numbers and a high proportion of neutrophils or can be normal, depending on the area of lung lavaged. Therefore, the bronchoalveolar lavage procedure is a very specific but not very sensitive test for pneumonia in horses. Abnormal lavage fluid is helpful diagnostically, whereas normal results do not exclude the presence of foci of pulmonary disease. The lavage samples may be normal in horses affected with pneumonia or pleuropneumonia and, because
of these false-negative results, this is not the best diagnostic technique to evaluate a horse with pneumonia. In contrast, the tracheobronchial aspirates are more sensitive and most horses with pneumonia have cytological abnormalities.

Endoscopic bronchoalveolar lavage

Endoscopic bronchoalveolar lavage has the advantage of permitting visual examination of the airways during the procedure and selection of the region of the lung to be lavaged. This technique does require access to sophisticated endoscopic equipment. The technique described below for horses can be modified for use in other species.

Horses for bronchoalveolar lavage should be appropriately restrained. Sedation is usually essential and is achieved by administration of alpha-2-agonists. Co-administration of narcotics is recommended by some authorities to reduce the frequency and severity of coughing. Butorphanol tartrate 10 mg for a 400 kg horse is recommended, although this drug is not as effective as intra-tracheal lidocaine at reducing the frequency or severity of coughing when combined with detomidine for collection of bronchoalveolar lavage fluid. Effective suppression of coughing during collection of bronchoalveolar lavage fluid can be achieved by instillation of lidocaine (60 mL of a 0.7% solution – made by diluting 20 mL of 2% lidocaine solution by addition of 40 mL of isotonic saline). The lidocaine solution is administered as the endoscope enters the rostral trachea. A twitch can be applied to the nares. The endoscope must be at least 2 m in length and the external diameter should be 10–15 mm. Endoscopes of 10 mm diameter will pass to about the fifth-generation bronchi, whereas endoscopes of larger diameter will not pass quite as far into the lung. The endoscope is passed until it wedges and then 300 mL of warmed (to reduced bronchospasm) isotonic saline is introduced in 5 x 60 mL aliquots. Air is infused after the last aliquot to ensure that all fluid is instilled. After the horse has taken between one and three breaths the fluid is withdrawn and the aliquots are mixed. There is no difference in the cytological composition of the first and subsequent aliquots.

Blind bronchoalveolar lavage

Commercial bronchoalveolar lavage tubes are available for use in horses, and are suitable for use in adult cattle and calves. The tubes are made of silicone and are therefore considerably more pliable than stomach tubes (which are not suitable for this procedure). The tubes are 2 m in length and have an external diameter of about 8 mm. The horse is restrained and sedated as for endoscopic bronchoalveolar lavage and the tube is passed through one nostril into the trachea. The tube is then advanced until it wedges, evident as no further insertion of the tube with mild pressure. Continued vigorous attempts to pass the tube can result in the tube flexing in the pharynx and a loop of the tube entering the mouth. After the tube wedges, the cuff on the tube is inflated to prevent leakage of fluid around it. 300 mL of warm isotonic saline is instilled, the tube is flushed with air and fluid is aspirated. The fluid should be foamy and, if cell counts are high, slightly cloudy.

Bronchoalveolar lavage can be performed in conscious sheep by insertion of 1.7 mm external diameter polyethylene tubing through a cannula inserted percutaneously in the trachea. The tubing is inserted until resistance is detected (about 40–45 cm in an adult sheep) and the lung is lavaged with 30 mL of sterile isotonic saline.

Laboratory assessment of tracheobronchial secretions

A problem with comparison of cell counts of bronchoalveolar lavage fluid reported by different authors is the use of inconsistent quantities of fluid to perform the lavage. The use of different volumes alters the extent of dilution of the fluid. There is a need for uniformity in technique. An approach to this problem has been to measure substances in the bronchoalveolar lavage fluid that can provide an indication of the extent of dilution of the sample. Both endogenous (urea, albumin) and exogenous (inulin, methyl blue) markers have been used.

Dilution factors using urea concentration in plasma and bronchoalveolar lavage fluid appear to be useful. The assumption is that urea concentrations in bronchial and alveolar secretions will be identical to that in plasma. The formula for correcting for dilution that occurs during collection of bronchoalveolar lavage fluid is:

\[ \text{Dilution factor} = \frac{\text{Urea concentration in bronchoalveolar lavage fluid}}{\text{Urea concentration in plasma}} \]

where urea concentration in bronchoalveolar lavage fluid and in plasma is expressed in the same units. The volume of the pulmonary epithelial lining fluid can then be calculated:

\[ \text{Pulmonary epithelial lining fluid volume} = \text{dilution factor} \times \text{volume of bronchoalveolar lavage fluid} \]

Samples for cytology are submitted for preparation involving centrifugation of the sample to concentrate cells for preparation of slides for staining and microscopic examination. At least for samples from horses, examination of smears made directly from the sample, without centrifugation, is diagnostically useful. As for tracheal fluid, the proportion of mast cells in equine bronchoalveolar lavage fluid is underestimated if cells are stained with fast Romanowsky stain (Diff-Quik®). Diagnostic value

The aspirates from normal animals contain ciliated columnar epithelial cells, mononuclear cells and a few neutrophils with some mucus. The concentration of the cells depends on the volume of fluid infused and the disease status of the animal. Representative values for various species are listed in Table 10.3. The general pattern is that animals with inflammatory airway disease, either infectious or non-infectious, have a higher proportion of neutrophils than do disease-free animals. However, ranges of normal values vary considerably depending on the species, the age of the animal and its management (primarily housing conditions). Care should be taken not to overinterpret findings on examination of tracheal aspirates or bronchoalveolar lavage fluid. While there is good correlation between microbiological results and cell counts in bronchoalveolar lavage fluid of calves with pneumonia and Thoroughbred race horses with inflammatory airway disease, this association might not hold for all diseases or species.

Thoracentesis (pleurocentesis)

Paracentesis of the pleural cavity is of value when the presence of pleural fluid is suspected and, in the absence of ultrasonographic examination, needs to be confirmed, and when sampling of pleural fluid for cytological and bacteriological examination is indicated. The primary indication for sampling pleural fluid is the presence of excess pleural fluid. Sampling of pleural fluid is usually accompanied by therapeutic drainage, in which case the cannula used for sampling is larger than if only collection of pleural fluid is desired. Contraindications are minimal, especially if the procedure can be performed under ultrasonographic guidance. The principal contraindication is the inability to restrain an unruly animal, as this increases the risk of laceration of the lung or a coronary vessel, or cardiac puncture. Complications include hemorrhage from lacerated intercostal or pleural vessels, pneumothorax secondary to laceration of the lung or introduction of air through the cannula, cardiac puncture and sudden death, irritation of the myocardium and ventilricular arrhythmia (premature ventricular contractions), or coronary artery laceration and subsequent cardiac tamponade and death. There is a risk of cellulitis at the site of access.

NR, not reported
of centesis, especially if indwelling cannulas are maintained for more than a day.

The procedure is performed with the animal standing. Sedation or systemic analgesia is usually not needed, unless it is medically indicated or the animal is not easily restrained. The equipment for sampling of pleural fluid from adult horses or cattle is a blunt 10–15 cm cannula of approximately 3 mm diameter (such as a bovine test cannula) or a 7.5 cm spinal needle. The blunt-tipped cannula is preferred because use of it reduces the risk of laceration of vital structures. A three-way stopcock or similar device should be attached to the hub of the needle or cannula and closed to prevent aspiration of air when the pleural cavity is entered. The site for centesis is best identified by ultrasonographic examination of the thorax or, if that is not available, by percussion and auscultation of the chest to identify the fluid level. A commonly used site is the seventh intercostal space on the left side and the sixth intercostal space on the right side. The skin should be clipped of hair and aseptically prepared. The region can be anesthetized with approximately 10 mL of 2% lidocaine, meperidine or similar product. The cannula or needle should be introduced over the rib and then directed cranial to the rib (the intercostal vessels and nerves course along the caudal edge of the rib). If a cannula is used then a slight ‘popping’ sensation is felt as the cannula perforates the parietal pleura. A syringe is attached to the cannula or needle and fluid is aspirated from the pleural space.

Collected fluid should be examined visually. Normal pleural fluid, which is present in small quantities in normal animals, is clear and slightly yellow. Abnormal fluid can be bloody, thick and yellow, suggestive of purulent material, or flocculent. The material should be smelled – a foul odor is usually present when the pleural fluid is infected by anaerobic bacteria and is a sign of a poor prognosis. Cytological examination should be performed, including white cell count and measurement of total protein concentration. Ancillary measurements on pleural fluid include pH, PCO₂, PO₂, bicarbonate, glucose and lactate. Sterile pleural fluid has a pH, PO₂ and PCO₂ and lactate, glucose and bicarbonate concentrations similar to those of venous blood. Infected pleural fluid is acidic, hypercarbic and has an increased concentration of lactate and decreased concentrations of bicarbonate and glucose compared to venous blood. Pleural fluid should be cultured for aerobic and anaerobic bacteria and mycoplasmas. Antimicrobial susceptibility should be determined for isolated organisms. Fungal cultures are rarely indicated.

Ultrasound-guided needle puncture of a suspected lung abscess to determine the species of bacteria present is sometimes practiced but there is the risk that infection will be spread to the pleura by this technique. This technique is not recommended as a routine procedure as microbiological examination of tracheal aspirates will probably yield the offending bacteria.

**PULMONARY FUNCTION TESTS**

Pulmonary function tests provide quantitative assessment of pulmonary ventilatory function through measurement of expired and inspired gas volumes, intrathoracic pressures and derivations of these variables – sometimes referred to as pulmonary mechanics. The techniques are widely used in research into pulmonary diseases, especially heaves, in horses, and have been adapted for use in ruminants. A relatively simple assessment of pulmonary function is measurement of pleural pressure changes during respiration. This can be achieved by either insertion of a blunt cannula through the intercostal space or passage of a balloon catheter into the thoracic esophagus. The pressure changes during respiration are then recorded and the maximal pressure change between inspiration and expiration is calculated. The pressure change is closely correlated with airway resistance to airflow and is an excellent indicator of the severity of bronchoconstrictive diseases.

More complex measurements are made by application of an airtight face mask containing a flow meter to the animal. Combined with measures of airway pressure, air flow during tidal breathing yields measures of tidal volume, minute volume, respiratory rate, pulmonary resistance and pulmonary dynamic compliance. Measurements made with the animal at rest are relatively insensitive to small changes in pulmonary function and the sensitivity of these tests to detect heaves is low. The sensitivity of changes in maximal pleural pressure and resistance of the lower airways are 44% and 22%, respectively. The sensitivity of the test can be increased by measuring these variables during exercise. Measurement of pulmonary mechanics in horses with heaves is reproducible over both short (hours) and long (months) periods of time, indicating the usefulness of these techniques for monitoring of disease progression and response to therapy.

Measurement of flow-volume loops has been performed for both stationary and exercising horses. A number of variables are derived from these measures and used as indicators of pulmonary function. However, the large variability in these measures in stationary horses (16–32%) severely limits the utility of this test to detect mild or subclinical respiratory disease. Similarly, flow–volume loops in exercising horses with obstructive lung disease of moderate severity do not differ markedly from those of the same horses when they do not have lung disease. Flow–volume loops have limited use in evaluation of lung function in animals.

Other tests of pulmonary function include the nitrogen dilution test and the single-breath diagram for CO₂. For the nitrogen dilution test concentrations of nitrogen in exhaled air are measured while the animal breathes 100% oxygen. A number of variables are calculated from the decay curve of nitrogen concentration in exhaled air, including the functional residual capacity. There are clinically significant differences between animals with normal respiratory function and those with pulmonary disease. However, this test is not readily adapted for routine clinical use. Volumetric capnography is the graphic examination of expired breath CO₂ concentrations versus expired volume to create a single-breath diagram for CO₂. The results are divided into phase I, which represents the relatively carbon-dioxide-free air from the proximal or orad conducting airways, phase II, which is the transitional phase, and phase III, which is the carbon-dioxide-rich air from the alveoli. Measures of pulmonary function obtained include estimates of dead space ratio, physiological dead space volume and alveolar efficiency. The clinical utility of this test and its ability to detect mild or subclinical disease in animals have not been demonstrated.

**Impulse oscillometry** offers the potential of being a potentially clinically useful test of respiratory function in both horses and cattle. The test measures impedance of the respiratory system and provides estimates of respiratory resistance and reactance. The technique has the advantage of being more sensitive to changes in pulmonary function than measurement of pleural pressure changes, minimally influenced by respiratory rate and tidal volume and is relatively easier to perform than more complex measures of respiratory mechanics. The test involves fitting an airtight facemask containing a pneumotachograph for measurement of respiratory volumes and tubing to a horse. The tubing is attached to a loudspeaker, which is used to generate square-wave signals containing harmonics between 0 and 10 Hz. Information from the system is analyzed using a computer program and indices of pulmonary resistance and reactance are determined.
The forced oscillation technique in feedlot cattle with naturally occurring shipping fever indicates the presence of a large increase in pulmonary resistance and a decrease in dynamic compliance with obstructive lung disease located mainly at the level of large airways but also in small airways. The clinical utility of the technique remains to be determined. The sensitivity of these tests can be increased by provocative tests in which animals are administered agents, such as histamine or methacholine, that cause bronchoconstriction in animals with reactive airways.

Measurement of forced expiratory flow-volume curves and forced vital capacity in horses is a sensitive indicator of bronchoconstriction. The test involves the heavily sedated horse having a nasotracheal tube inserted. The nasotracheal tube is then attached to a large vacuum reservoir and a valve is opened abruptly. The maximum rate of forced expiratory airflow is measured and various variables indicative of pulmonary function are calculated, including forced expiratory volume in one second (FEV1). The clinical utility of this test of pulmonary function is limited by the extensive instrumentation of the animal and the need for sophisticated electronics.

A portable system for monitoring cardiovascular and respiratory function in large animals is available. Pulmonary function testing of cattle is also being examined and may provide some understanding of the pathophysiology of respiratory tract disease. Calves between 1 and 8 months of age with chronic respiratory disease have

- Significantly reduced inspiratory and expiratory times and tidal volume
- Significantly increased respiratory frequency and airway resistance
- More negative transpulmonary pressure values when compared to predicted values for the same calves.

Arterial oxygen and carbon dioxide tensions are the only variables which correlate with clinical scores.

**ARTERIAL BLOOD GAS ANALYSIS**

Measurement of $P_{O_2}$, $P_{CO_2}$ and arterial oxygen content ($C_{O_2}$) provides valuable information about pulmonary function and oxygen delivery to tissues. The arterial oxygen tension and arterial oxygen content are not equivalent. The arterial oxygen tension ($P_{O_2}$) is a measure of the partial pressure of oxygen in arterial blood determined by the amount of oxygen dissolved in the blood (not the amount bound to hemoglobin) and the temperature of the blood - it is not a direct measure of arterial oxygen content. Arterial oxygen content is the amount of oxygen per unit of blood and includes both dissolved oxygen and that bound to hemoglobin. The oxygen tension can be viewed as the driving force for diffusion of oxygen from capillaries into mitochondria (in which the oxygen tension is about 2 mmHg), whereas the oxygen content is the amount of oxygen delivered to tissue. Both are important measures of pulmonary function and oxygen delivery to tissue.

Measurement of oxygen tension in blood is achieved by analysis of an appropriately collected sample of arterial blood using a blood gas analyzer (oxygen electrode). Instruments designed for medical or veterinary clinical use measure pH, $P_{O_2}$ and $P_{CO_2}$ at a temperature of 37°C. Depending on the software included with the instrument, various derived values are also reported, including bicarbonate concentration, base excess and oxygen saturation. It is important to understand that oxygen saturation reported by blood gas instruments is a calculated value and might not be correct. Oxygen saturation is measured by a co-oximeter, which is different from a blood gas machine, and the amount of oxygen carried by hemoglobin is then calculated from this value and the assumption that each gram of hemoglobin, when fully saturated, carries approximately 1.34–1.39 mL of oxygen. The total oxygen content of blood is calculated by adding the amount carried by hemoglobin to the amount of oxygen dissolved in the aqueous phase of the blood. The formula is:

$$O_2\text{ content} = (S\dot{O}_2 \times 1.34 \times [Hb]) + (0.003 \times P_{O_2})$$

where $O_2$ content is in mL/100 mL, $S\dot{O}_2$ is the arterial oxygen saturation (%), 1.34 is the amount of oxygen carried by fully saturated hemoglobin (mL/g), [Hb] is the concentration of hemoglobin in blood (g/100 mL), 0.003 is the amount of oxygen dissolved in the aqueous phase of 100 mL of blood for each 1 mmHg increase in $P_{O_2}$, and $P_{O_2}$ is the oxygen tension in arterial blood. The appropriate substitutions can be made to calculate the oxygen content of venous blood.

The oxygen content of arterial blood is the critical factor (with cardiac output) in determining oxygen delivery to tissues. However, measurement of arterial oxygen content is not as readily accomplished as measurement of arterial oxygen tension. Therefore, in animals with normal hemoglobin concentration and function the arterial oxygen tension is used as a surrogate measure of arterial oxygen content. In doing so, it must be recognized that the extent of hemoglobin saturation with oxygen is dependent on both the affinity of hemoglobin for oxygen and the oxygen tension of the blood. The oxygen tension/percentage saturation relationship is sigmoidal, with 50% saturation occurring at about 30 mmHg in most species (there are minor variations) and 80% saturation at a $P_{O_2}$ of 45–55 mmHg. The sigmoidal shape of the oxygen–hemoglobin saturation curve has important clinical consequences. Small decrements in $P_{O_2}$ from normal values (usually 95–105 mmHg in animals breathing ambient air at sea level) have a minimal effect on oxygen content of blood. Many modern blood gas analyzers have software that calculates oxygen content of blood, but it must be recognized that these calculations often use an assumed, not measured, hemoglobin concentration (usually 15 g/dL) and values for the human $S\dot{O}_2$–$P_{O_2}$ relationship. These assumed values may not be correct for animals and one should always check the assumptions used to calculate oxygen content of blood before accepting and acting on those values. Direct measurement of blood oxygen content is restricted to research laboratories – indirect estimates gained from oxygen saturation and hemoglobin concentration are usually sufficiently accurate for clinical use.

The oxygen tension in blood is proportional to the amount of oxygen dissolved in the aqueous phase of the blood and the temperature of the blood. For a given amount of oxygen dissolved in blood, the tension varies according to the temperature of the animal. Almost all blood gas analyzers measure the $P_{O_2}$ at 37°C. If the animal’s body temperature is markedly different from that then the reported $P_{O_2}$ can be erroneous. For instance, the $P_{O_2}$ of a horse with a body temperature of 40°C measured using an analyzer with a temperature of 37°C would be 80 mmHg (the $P_{CO_2}$ would be 35 mmHg). If the $P_{O_2}$ was adjusted for the difference between the horse’s body temperature and that of the analyzer, then the reported $P_{O_2}$ would be 100 mmHg (and the $P_{CO_2}$ would be 44 mmHg). Failure to make the appropriate temperature corrections can result in errors of 6–7% per °C. When interpreting blood gas values, attention should be paid to the temperature of the animal and consideration given to adjusting gas tension values according to the animal’s body temperature. This is probably only clinically important when there are extreme deviations from normal temperature and oxygen tension. Most blood gas analyzers include software that makes the appropriate corrections.

The arterial oxygen tension is determined in the alveolus by the alveolar
oxygen tension and the alveolar-arterial difference. The alveolar oxygen tension \( (P_{A}O_{2}) \) can be calculated from:

\[
P_{A}O_{2} = F_{O_{2}}(P_{B} - P_{H_{2}O}) - (P_{A}CO_{2}/RQ),
\]

where \( F_{O_{2}} \) is the inspired oxygen fraction (21% for ambient air), \( P_{B} \) is the barometric pressure (760 mmHg at sea level), \( P_{H_{2}O} \) is the partial pressure of water vapor in the alveolar air (47 mmHg at 37°C), and RQ is the respiratory quotient (usually assumed to be 0.8 for resting animals). The alveolar-arterial \( PO_{2} \) difference \( (A-a PO_{2}) \) is calculated:

\[
A-a PO_{2} = PO_{2} - PO_{2}.
\]

The A-a \( PO_{2} \) difference has clinical significance in that it is an indicator of pulmonary function that is somewhat independent of inspired oxygen fraction and is therefore useful in animals being supplemented with oxygen (there is a small increase in A-a difference with marked increases in \( F_{O_{2}} \)). Increases in A-a \( PO_{2} \) difference are indicative of ventilation/perfusion mismatches, with the A-a \( PO_{2} \) difference increasing with worsening ventilation/perfusion abnormalities.

**Normal values**

Values obtained from clinically normal animals breathing room air at sea level vary slightly between species, with most animals having an arterial \( P_{A}O_{2} \) of 95-105 mmHg and a \( P_{A}CO_{2} \) of 35-45 mmHg. Oxygen saturation in clinically normal animals breathing air at sea level is above 98% and oxygen content of arterial blood is 16-24 mL/dL of blood (this depends on the hemoglobin concentration in blood). The difference in oxygen content of arterial and mixed venous blood is usually 4-8 mL/dL of blood. Values can be influenced substantially by changes in physiological state (exercise, hyperpnea), positioning, pulmonary disease and altitude (Table 10.4). Positioning of the animal can be important, especially in neonatal foals, in which the compliant chest wall can impair ventilation in laterally recumbent foals—foals have lower arterial oxygen tension when in lateral recumbency than when in sternal recumbency.

**Collection of arterial blood gas samples**

Arterial samples can be collected from any of the appropriate peripheral arteries, which vary depending on species. An arterial sample is representative of aortic blood in almost all instances. Samples can be collected from the carotid, transverse facial, metacarpal and metatarsal arteries in horses and foals, and from the carotid, radial and coccygeal arteries in cattle and calves. Minimally invasive arterial access is difficult in pigs.

Samples should be collected in glass or plastic syringes in which the dead space has been filled with heparin solution. Typically, a 3 mL plastic syringe containing approximately 0.1 mL of sodium heparin and attached to a 22-25-gauge needle is used. All air should be expelled from the syringe before collection of the sample, and care should be taken not to introduce air into the syringe until blood gas tensions are measured. Air in the syringe will increase the measured oxygen tension of blood from normal animals. The sample should be measured as soon after collection as possible (within minutes). If immediate analysis is not available, the sample should be stored in iced water until analysis to prevent consumption of oxygen, production of carbon dioxide and a decrease in pH. Storage of arterial samples in plastic syringes in iced water can increase the oxygen tension from 100 mmHg to 109 mmHg in as little as 30 minutes. This does not occur when samples are stored in glass syringes in iced water. The pH and \( P_{A}CO_{2} \) are not affected by the type of syringe.

**VENOUS BLOOD GAS ANALYSIS**

Measurement of gas tensions in venous blood is of limited value in assessing pulmonary function because of the extensive and variable effects of passage through the capillary beds on gas tensions. However, measurement of venous oxygen tension, saturation or content can be useful in assessment of the adequacy of oxygen delivery to tissue. The oxygen tension, saturation and content of venous blood depends on the extent of oxygenation of arterial blood, the blood flow to the tissues, the metabolic rate of the tissues drained by the veins from which blood is sampled, and the transit time of blood through capillaries. The multiplicity of these factors means that determining the precise reasons for abnormalities in venous blood gas tensions is not possible. However, some generalizations can be made about venous oxygen tension, saturation and content.

In normal, resting animals, oxygen delivery to tissues exceeds oxygen needs (demand) of the tissue, with the result that venous blood draining these tissues is only partially desaturated. Hence, venous blood from the pulmonary artery (mixed venous blood) has oxygen tension, saturation and content of approximately 35-45 mmHg, 80-90% and 12-18 mL/100 mL (the latter depending on hemoglobin concentration in addition to hemoglobin saturation). However, in situations in which oxygen delivery to tissue is decreased to levels that just meet or do not meet the oxygen needs of tissue, there is extraction of a greater proportion of the oxygen in blood and venous oxygen tension, saturation and content decline and the arterial-venous difference in oxygen content increases. Reasons for oxygen delivery to tissue not meeting the oxygen needs of tissue include anemia or decreased \( P_{A}O_{2} \). Additionally, tissues with a high metabolic rate, such as exercising muscle, have high oxygen demands that can outstrip delivery.

Ideally, whole body assessment of oxygen delivery by measurement of venous blood gas tensions is best achieved by examination of mixed venous blood. Mixed venous blood represents an admixture of blood draining all tissues and is collected

---
from the pulmonary artery (although samples collected from the right ventricle or atrium are also appropriate in most instances). While this blood is optimal for assessment of oxygen delivery to tissue, collection of mixed venous samples is not routine because of the need for catheterization of the pulmonary artery. Samples from peripheral veins are therefore used, but care should be taken when interpreting these values as venous blood gas tensions can vary considerably among veins.  

For animals with normal circulatory status, blood gas tensions in jugular vein blood are likely to be reasonable estimates of mixed venous gas tensions. However, if circulatory function is not normal, then samples from peripheral veins may not be indicative of values in mixed venous blood.  

Samples for venous blood gas analysis should be collected into syringes in which the dead space is filled with sodium or lithium heparin solution. The volume of heparin should not be more than 2% of the amount of blood. Samples should be processed promptly. If samples cannot be processed within an hour they should be stored in iced water. Samples stored in iced water for 24 hours have values that are minimally different from those before storage, while samples stored at 25°C change markedly in 2-3 hours.  

Pulse oximetry

Pulse oximeters are devices for measurement of blood oxygen saturation that attach to skin or mucous membranes and sense the absorption spectrum of light by hemoglobin (the same principle is used in bench-top oximeters) in the underlying tissues. The devices are widely used for noninvasive monitoring of oxygenation in humans and have been adopted for use in animals. However, important challenges to their use exist in animals, not least of which is the presence of hair and densely pigmented skin in most farm animals. The devices have important deficiencies when used in foals and adult horses but those applied to the ear, lip or tongue of foals have good sensitivity and specificity for detecting arterial $S_0_2$ of less than 90 mmHg (12 kPa). The devices consistently underestimate arterial $S_0_2$ at low saturations. Care should be taken when using these devices to monitor arterial hemoglobin saturation in animals.

BLOOD LACTATE CONCENTRATION

Measurement of blood lactate concentration is useful in assessing the adequacy of oxygen delivery to tissues. Hypoxia causes a shift to anaerobic metabolism and the production of lactate. Lactate production is related to the severity and duration of hypoxia, with more severe hypoxia resulting in greater accumulation of lactate in tissues and its subsequent diffusion or transport into blood. Hypoxia also reduces the rate of removal of lactate from blood. The combination of increased production and decreased removal causes lactate to accumulate in blood. Measurement of blood lactate concentrations (which are usually lower than plasma lactate concentrations) is gaining increasing clinical usefulness as ‘point-of-care’ analyzers become more readily available and testing more affordable.

Samples for measurement of blood lactate can be collected into syringes containing heparin solution (as used for measurement of blood gas tensions) if the sample is to be analyzed within 30 minutes. Samples should be stored in iced water until analysis. Prolonged storage at room temperature results in increases in blood lactate concentration. If sample collection is anticipated to be delayed, then samples should be collected into evacuated tubes containing sodium fluoride and potassium ethylenediamine tetraacetic acid (EDTA) – the sodium fluoride inhibits glycolysis. However, plasma lactate concentrations collected in these tubes are approximately 10% lower than in samples collected into tubes containing heparin – probably because of the osmotic effect of sodium fluoride/potassium EDTA on red cells. Samples for clinical analysis should be collected into syringes containing a heparin solution and analyzed within 30 minutes of collection. Measurement of blood or plasma lactate concentrations can be made using ‘point-of-care’ analyzers, although these can yield results that differ markedly from traditional analyzers, especially in animals with extreme values for hematocrit (severe anemia or polycythemia). Ideally, blood and plasma lactate concentrations should be measured only on analyzers that have been validated for the species and clinical situation being studied.

Blood lactate and plasma lactate concentrations are not equal, with blood lactate concentration being lower because of the dilutional effect of red blood cells, which have a lower lactate concentration than plasma. However, most clinical assessments are based on blood lactate concentrations. Mixed venous or arterial blood lactate concentrations in most farm animal species are less than 2 mmol/L in normal, healthy animals. Tissue hypoxia, in addition to other conditions such as toxinemia and septic shock, can increase blood lactate concentration. Blood lactate concentrations between 2 and 4 mmol/L should be interpreted with caution whereas values above 4 mmol/L are indicative of clinically important disruption of oxygen transport and cellular metabolism. Repeated measurements over time can be useful for assessing progression of disease or efficacy of treatment. For instance, plasma lactate concentrations above 4 mmol/L in cattle with pneumonia are predictive of death within 24 hours.

COLLECTION AND ANALYSIS OF EXHALED BREATH CONDENSATE

Collection and analysis of exhaled breath condensate has use primarily in research studies at the current time. Breath condensate is collected and analyzed for markers of pulmonary or systemic disease. Induction of pneumonia in calves by infection with Pasteurella multocida causes increases in concentration of leukotriene B4 in breath condensate. Horses with heaves have higher concentrations of hydrogen peroxide than normal horses – probably a result of the airway neutrophilia in affected animals.

LUNG BIOPSY

Percutaneous biopsy of the lung is useful in confirming diagnosis of lung disease by providing tissue for histological and microbiological examination. The procedure in cattle, sheep and horses is described. Indications for the procedure include the presence of diseases of the lungs in which a diagnosis cannot be arrived at through other forms of examination, including tracheal aspiration or bronchoalveolar lavage. It can also be used for assessing the severity of histological changes and response to therapy. The procedure is best suited for widespread diseases of the lung, but can be used for diseases that produce focal lesions if the biopsy is performed with ultrasonographic guidance. Contraindications include abnormalities in clotting function, pneumothorax and severe respiratory distress. The danger in performing lung biopsy in animals in severe respiratory distress is that complications of biopsy, such as pneumothorax, hemotherax or hemorrhage into airways, could further impair lung function and cause the death of the animal. Complications include pneumothorax, hemotherax, hemorrhage into airways with subsequent hemoptysis or epistaxis, pulmonary hematoma and dissemination of infection from infected lung to the pleural space. Pneumothorax, which is usually not clinically apparent, occurs in most horses in which the procedure is performed. Coughing and epistaxis occur in about 20% and 10% of horses, respectively. Life-threatening hemorrhage occurs uncommonly (≈ 2% of cases). Bleeding into the airways, detected
Principles of treatment and control of respiratory tract disease

TREATMENT OF RESPIRATORY DISEASE

Treatment of diseases of the lower respiratory tract depends on the cause of the disease. However, the common principles are:

- Ensure adequate oxygenation of blood and excretion of carbon dioxide
- Relieve pulmonary inflammation
- Effectively treat infectious causes of respiratory disease
- Relieve bronchoconstriction
- Supportive care to minimize demands for respiratory gas transport

Respiratory gas transport

Cause of acute death in animals with respiratory disease is usually failure of transport of respiratory gases with subsequent hypoxemia and hypercapnia. Treatment of failure of oxygenation of blood and excretion of carbon dioxide can be achieved through administration of supplemental oxygen or mechanical ventilation. The reasons for failure of respiratory gas transport are discussed above, and should be considered when therapy of an animal with respiratory disease and hypoxemia with or without hypercarbia is planned. Animals with hypercarbia and hypoxemia are probably hypoventilating and consideration should be given to increasing the animal's minute ventilation through relief of airway obstruction (e.g. by foreign bodies or bronchoconstriction), improvement in function of the respiratory muscles (restore hydration, maintain normal blood concentrations of electrolytes, including calcium), and positional adjustments (foals have better respiratory function when in sternal recumbency). Artificial ventilation should be considered, but is impractical for long-term treatment in animals other than those housed in referral centers. Ventilation/perfusion abnormalities cause hypoxemia with normal or only slightly elevated $P_{CO_2}$ in most affected animals. Oxygen therapy can be useful in ameliorating or attenuating the hypoxemia due to ventilation/perfusion abnormalities.

OXYGEN THERAPY

The principal treatment for hypoxemia caused by diseases of the lungs is the administration of oxygen. Oxygen therapy is not often used in large animals in field situations but the use of a portable oxygen cylinder may find a place in tending animals over a period of critical hypoxia until inflammatory lesions of the lungs subside. It has been used most often in valuable calves and foals. Oxygen therapy must be given continuously, requires constant or frequent attendance on the animal, and can be expensive. Supplemental oxygen is usually administered through a nasal cannula with the tip placed in the nasopharynx, through a mask or through a cannula inserted percutaneously in the trachea. The use of an oxygen tent is impractical.

Oxygen therapy is useful only when hypoxemia is attributable to failure of oxygen transport in the respiratory system. It is of no value when the hypoxia is due to toxins that interfere with oxygen metabolism in tissues (e.g. cyanide). Oxygen therapy will only minimally increase oxygen transport in animals with anemia, abnormal hemoglobin (methemoglobinemia) or cardiovascular shock (stagnant hypoxia). Cases of pneumonia, pleurisy, and edema and congestion of the lungs are most likely to benefit from provision of supplemental oxygen.
Oxygen is often administered to newborn animals, either during resuscitation after birth or in those animals with respiratory disease. The value of supplemental oxygen in increasing \( P_{\text{O}_2} \) has been examined in foals, but the recommendations probably apply to newborns of other species as well. Both a facemask and nasopharyngeal tube are effective in increasing \( P_{\text{O}_2} \) when oxygen is administered at 10 L/min. The ability to elevate arterial oxygen increases with age from birth to 7 days of age because of the existence of right-to-left shunts in the newborn foal. Maximal changes in arterial oxygen tension occur within 2 minutes of the start of supplementation. In normal foals a flow rate of 2 L/min increases arterial oxygen tension, but responses in sick foals are often attenuated as a result of positional effects on gas exchange (recumbency) and other causes of hypoventilation. Nasal insufflation improves arterial oxygen tensions and acid–base status in mild to moderately affected foals but may not be sufficient for oxygenation of foals with severe impairment of gas exchange. Intranasal catheters are also difficult to maintain in active sucking foals and require the use of higher oxygen flow rates to achieve beneficial effects. Oxygen should be delivered through a system that includes a humidifier so the insufflated gas is humidified and therefore drying of the respiratory mucosa is minimized.

A transtracheal oxygen delivery system has been used in foals with pneumonia and rapidly progressive dyspnea and hypoxemia despite intranasal oxygen therapy. A catheter is inserted into the midcervical trachea and directly distally in the tracheal lumen for approximately 25 cm. The catheter is attached to about 6 m of oxygen tubing and suspended above the foal, allowing it to move around the stall and suck the mare for up to 6 days without dislodging the catheter. This system was more effective than nasal insufflation in increasing arterial oxygen tension, probably because the catheter tip is in the distal trachea and bypasses a significant length of dead space that would not be oxygenated were the oxygen delivered into the nasopharynx.

In foals with neonatal respiratory distress, signs of respiratory failure may be evident at birth or several hours after birth. Tachypnea, shallow and paradoxical respiration, an expiratory grunt with accentuated abdominal effort, and cyanosis are all common. Management of foals with respiratory distress includes oxygen therapy but, when the distress is severe, oxygen insufflation alone is insufficient to improve the \( P_{\text{O}_2} \) which is usually 45–60 mmHg (6.0–8.0 kPa). The atelectasis and alveolar hypventilation worsen, resulting in progressive hypoxemia and respiratory acidosis, which requires ventilatory assistance by the use of continuous positive airway pressure.

In cattle and adult horses the nasal tube must be inserted into the nasopharynx because passage short of this causes excessive waste of oxygen. The length of tube inserted should equal the distance from the nostril to a point one-third of the way from the lateral canthus of the eye to the base of the ear. Insertion of a nebulizer in the system permits the simultaneous administration of antibiotics and moisture to prevent drying of the pharyngeal mucosa. The volume of oxygen used should be about 10–20 mL of oxygen per min per kg of body weight. Repeated measurement of arterial oxygen tension, if available, is useful for determining the flow rate. Arterial oxygen tension responds to changes in the rate of administration of oxygen within several minutes.

Oxygen toxicity is a risk in animals breathing pure oxygen for periods exceeding 1–2 days, but this rarely occurs in veterinary medicine because supplementation with oxygen does not result in the animal breathing pure oxygen (except for animals under general anesthesia).

**RESPIRATORY STIMULANTS**

Use of respiratory stimulants, including doxapram, picrotoxin, leptazol (Metrazol), nikethamide (Coramine), caffeine and amfetamine sulfate, which has been advocated in the past, is not useful or recommended in animals with hypoxemia due to respiratory disease. In these animals there is already maximal stimulation of the respiratory center and administration of drugs such as caffeine or doxapram is at best useless and at worst harmful, in that they can increase oxygen demand, in particular myocardial oxygen demand, thus exacerbating any oxygen deficit. The drugs might be useful in stimulating respiration in animals with pharmacological depression of the respiratory center by general anesthetics and sedatives.

**M E C H A N I C A L V E N T I L A T I O N**

Short-term mechanical ventilation can be achieved in neonates and small adults by use of a nasotracheal tube and a hand-operated bellows, which is usually in the form of a resilient bag equipped with a one-way valve. The animal’s trachea is intubated and the bag is connected and squeezed to supply a tidal volume of approximately 5–10 mL/kg BW at a rate of approximately 20 breaths per minute. Commercial bags (Ambubag) are available in a variety of sizes suitable for neonates and small ruminants. There is a simple device for respiratory resuscitation of newborn calves and lambs consisting of a mouthpiece, a nonreturn valve, a flange and an oral tube. Ventilation of larger animals requires use of compressed gases and appropriate valving systems, including a Hudson demand valve. In an emergency situation, artificial ventilation of neonates and small ruminants can be achieved by mouth-to-nose ventilation by the veterinarian. This should be done only with an awareness of the risks of disease transmission (e.g. a weak newborn calf could be infected by *Brucella* sp. or *Leptospira* sp.).

Prolonged mechanical ventilation is an activity requiring special equipment and expertise. It is indicated for the treatment of diseases of neonates, and perhaps adults, that cause hypoxemia and hypercarbia. There is usually a significant component of hypoventilation in these diseases and this is a prime indication for use of mechanical ventilation. An excellent example is the use of mechanical ventilation to treat foals with botulism. In experienced hands, this technique is effective. Because of the highly technical and demanding requirements for mechanical ventilation, the interested reader is referred to more detailed sources for descriptions of the methodology.

**A N T I - I N F L A M M A T O R Y T H E R A P Y**

Many infectious and noninfectious diseases of the lower respiratory tract have inflammation as a major component of the tissue response to the initial insult. Primarily inflammatory diseases include heave and inflammatory airway disease of horses. Inflammation is an important component of pneumonia and some of the allergic or toxic lung diseases. Suppression of the inflammatory response is indicated when the inflammatory response is exacerbating clinical signs of the disease through obliteration of alveoli (inflammatory atelectasis), blockage of airways by inflammatory exudates and infiltration of bronchial walls, and bronchoconstriction as a consequence of inflammation increasing airway reactivity. Administration of anti-inflammatory drugs is indicated as the definitive therapy in noninfectious inflammatory airway diseases (with control achieved by environmental controls, see below). Care must be taken that suppression of the inflammatory response does not impair innate and adaptive immune responses to infectious agents.

Anti-inflammatory drugs used in the treatment of diseases of the respiratory tract include glucocorticoids and nonsteroidal anti-inflammatory drugs (NSAIDs), with other agents such as leukotriene antagonists, interferon and cromolyn sodium used in particular situations.
Nonsteroidal anti-inflammatory drugs are useful in the treatment of infectious respiratory disease of cattle and horses, and likely other species. The drugs act by inhibiting the inflammatory response induced by the infecting organism and tissue necrosis. Meloxicam (0.5 mg/kg subcutaneously, once), when administered with tetracycline, improves weight gain and reduces the size of lesions in lungs of cattle with bovine respiratory disease complex over those of animals treated with tetracycline alone.\(^ {123}\) NSAIDs also improve the clinical signs of cattle with respiratory disease.\(^ {124}\) Use of these drugs is routine in horses with pneumonia or pleuritis.

Glucocorticoids are administered for control of inflammation in a variety of inflammatory lung diseases but notably heaves of horses and interstitial pneumonia of foals. Treatment can be administered orally, by intravenous or intramuscular injection, or by inhalation. Oral, intramuscular or intravenous administration results in systemic effects of the agents. Inhalation of glucocorticoids provides therapy directed to the site of the disease and minimizes, but does not always prevent, the systemic effects of the drugs. Drugs for inhalation are usually human preparations of fluticasone, beclomethasone and flunisolide that are available as metered-dose inhalers. The compounds are administered through a mask adapted so that a large proportion of the drug is inhaled. Anti-inflammatory responses in the airways are pronounced and result in marked improvement in respiratory function in horses with heaves (see Heaves, Recurrent airway obstruction).

**IMMUNOMODULATORS**

Interferon is used for the treatment of inflammatory airway disease in race horses and feedlot cattle with respiratory disease.\(^ {125,126}\) A dose of 50–150 IU of interferon-alpha administered orally once daily for 5 days reduced signs of airway inflammation in young Standardbred race horses.\(^ {127}\) Immune stimulation by injection of a suspension of Propionibacterium acnes has been investigated for treatment of chronic inflammatory airway disease in horses. The compound enhances expression of interferon-gamma and NK-lysin in peripheral blood mononuclear cells, increases the proportion of CD4\(^ +\) cells in peripheral blood and increases phagocytic activity of cells in peripheral blood.\(^ {128,129}\) Similar changes were detected in bronchoalveolar lavage fluid.\(^ {130}\) The effect on respiratory disease has yet to be definitively determined.

**ANTIMICROBIAL THERAPY**

Bacterial infections of the respiratory tract of all species are treated with antimicrobial agents given parenterally or, less commonly, orally. Individual treatment is usually necessary and the duration of treatment will depend on the causative agent and the severity when treatment was begun. In outbreaks of infectious respiratory disease the use of mass medication of the feed and water supplies may be advisable for the treatment of subacute cases and for convalescent therapy. The response to mass medication will depend on the total amount of the drug ingested by the animal and this is a reflection of the appetite or thirst of the animal, the palatability of the drug and its concentration in the feed or water. The choice of drug used will depend on its cost, previous experience on similar cases and the results of drug sensitivity tests if available. The individual treatment of all in-contact animals in an affected group may be useful in controlling an outbreak of respiratory disease such as shipping fever in feedlot cattle.

**Selection of antimicrobials** is based on the principles detailed in Chapter 4. Briefly, antimicrobials for treatment of bacterial respiratory disease should be active against the causative agent, should be able to achieve therapeutic concentrations in diseased lung and should be convenient to administer. The antimicrobials should be affordable and, if used in animals intended as human food, must be approved for use in such animals.

Antimicrobials for treatment of lung disease are preferably those that achieve therapeutic concentrations in diseased lung tissue after administration of conventional doses. This has been convincingly demonstrated for the macrolide (azithromycin, erythromycin, clarithromycin),\(^ {130}\) trimethoprim (tulathromycin)\(^ {130,132}\) and fluoroquinolone (danofloxacin, enrofloxacin)\(^ {133,134}\) antimicrobials, and florfenicol\(^ {135}\) in a variety of species. The beta-lactam antimicrobials (penicillin, cephalosporin) are effective in treatment of pneumonia in horses, pigs, and ruminants despite having chemical properties that do not favor their accumulation in lung tissue.

Routes of administration include oral (either individually or in medicated feed or water), parenteral (subcutaneous, intramuscular, intravenous) or by inhalation. Intratracheal administration of antimicrobials to animals with respiratory disease is not an effective means of achieving therapeutic drug concentrations in diseased tissue. Aerosolization and inhalation of antimicrobials has the theoretic advantage of targeting therapy to the lungs and minimizing systemic exposure to the drug. However, while administration by inhalation achieves good concentrations of drug in bronchial lining fluid, it does not penetrate unventilated regions of the lungs, in which case parenteral or oral administration of antimicrobials is indicated.

Aerosol administration of gentamicin to horses and ceftiofur sodium to calves with pneumonia has been investigated. Aerosol administration of gentamicin to normal horses results in gentamicin concentrations in bronchial lavage fluid 12 times that achieved after intravenous administration.\(^ {136}\) Aerosolized ceftiofur sodium (1 mg/kg) is superior to intramuscular administration in treatment of calves with Pasteurella (Mannheimia) haemolytica.\(^ {137}\)

**BRONCHODILATOR DRUGS**

Bronchoconstriction is an important component of the increased airway resistance present in many animals with disease of the lower respiratory tract. Administration of bronchodilators can relieve respiratory distress and improve arterial blood oxygenation. Bronchodilatory drugs are beta-2-agonists (clenbuterol, albuterol/salbutamol, terbutaline), parasympatholytic drugs (ipratropium, atropine) and methylxanthines (aminophylline, theophylline).

The indication for the use of bronchodilators is relief of bronchoconstriction. Bronchoconstriction is an important component of the pathophysiology of many diseases of the lungs and airways. Bronchodilators are used extensively in horses with heaves and inflammatory airway disease, and less so in animals with infectious diseases. Contraindications are few but caution should be exercised when using these drugs in animals that are severely hypoxicemic as the beta-2-agonists can transiently worsen gas exchange by increasing perfusion of nonventilated sections of the lung, and in pregnant animals, in which the tocolytic effect of the beta-2-agonists can delay parturition. The use of beta-2-adrenergic agonist bronchodilator drugs in food animals is not permitted in most countries because of the risk of contamination of foodstuffs intended for consumption by people. This is particularly the case with clenbuterol, a drug approved in many countries for use in horses that is administered to cattle illicitly as a growth promoter. People can be poisoned by clenbuterol in tissues of treated cattle.\(^ {138}\)

The beta-2-adrenergic agonists are potent and effective bronchodilators that can be administered orally, intravenously or by inhalation. These drugs also enhance mucociliary clearance of material from the lungs. Most administration is oral or by inhalation. Use of these drugs is restricted to horses and the drugs are discussed in the section on Heaves.
Parasympatholytic (anticholinergic) drugs relieve vagally mediated bronchoconstriction. Again, their use is restricted to horses. These drugs can cause tachycardia and gastrointestinal dysfunction, including ileus.

The methylxanthines are used in horses and have been investigated for use in cattle with respiratory disease. Their use in horses is mainly of historical interest because the availability of the more efficacious beta-2-adrenergic agonists and parasympatholytic drugs has superseded the use of methylxanthines. The use of theophylline in feedlot cattle with respiratory disease is of low viscosity and the use of a mucolytic agent in such cases would be of some value in cattle to increase mucociliary clearance. 141

Hyperhydration, the administration of large quantities of fluids intravenously, has been suggested as being useful in the treatment of horses with accumulation of excessive amounts of mucus or muco pus in the lower airways. However, experimental trials have demonstrated that this approach is not effective in horses with heaves. 142

Bronchomucotropic agents (expectorants) are administered with the intention of augmenting the volume of respiratory secretions by stimulating the mucus-producing cells and glands. Formerly called expectorants, they are supposed to increase the production of a less viscous mucus. These compounds include the iodides, and ammonium and glycerol guaiacolate, which are commonly found in cough mixtures. These are commonly used in farm animals, especially horses, although their efficacy is unknown.

Coughing is a common sign in animals with respiratory disease, and it is an important pulmonary defense mechanism, allowing the expulsion of mucus and foreign bodies. Antitussive (cough suppressant) drugs are infrequently used in large-animal medicine. These drugs should only be used when definitive therapy has been implemented for the underlying disease. Control of the underlying disease will in almost all instances resolve the coughing. It is not appropriate to use antitussive agents (butorphanol, codeine, diphenhydramine) to suppress a cough when the underlying cause is unknown or untreated.

SURFACANT
Surfactant is critical to normal alveolar function and a lack of this complex phospholipid results in progressive alveolar collapse. 143 Lack of surfactant is an important cause of respiratory disease in newborn animals, with those born prematurely being at increased risk. Attempts have been made to prevent acute respiratory disease in premature newborn foals, such as those delivered by cesarian section because of maternal disease, but the results have been disappointing. 144

SURGERY
Many conditions of the upper respiratory tract of horses are amenable to surgical correction. Tracheostomy is often used in the emergency or urgent relief of acute upper airway obstruction, and in the removal of large amounts of tracheal debris, such as occurs in animals with smoke inhalation. Drainage of excessive or infected pleural fluid can be therapeutic in animals with pleuritis.

GENERAL NURSING CARE
Animals with respiratory disease should have minimal or no enforced activity and environmental stressors should be minimized. One of the most important aspects of the treatment of respiratory tract disease in farm animals is the provision of a comfortable, well-ventilated environment during and after the disease episode. Affected animals should be placed in a draft-free area that is adequately ventilated and supplied with an abundance of bedding for comfort and warmth, particularly during convalescence. Feed and water should be readily available and dusty feeds avoided.

CONTROL OF RESPIRATORY DISEASE
Infectious diseases of the respiratory tract of farm animals are caused by a combination of infectious agents and pre-disposing causes such as inclement weather, the stress of weaning or transportation and poorly ventilated housing, each of which can weaken the defense mechanisms of the animal. Prevention and control of these diseases include:

- Minimizing exposure to inciting agents (infectious or physical)
- Maximizing innate resistance by ensuring that the animals are in excellent general health through attention to nutrition, housing and animal welfare
- Maximizing adaptive resistance by the administration of effective vaccines such that maximal resistance is produced to coincide with the time of greatest risk of the disease.

IMPORTANCE OF DIAGNOSIS
For some complex respiratory diseases of food animals it is becoming increasingly more difficult to obtain a definitive etiological diagnosis because some of the common diseases appear to be caused by multiple infections rather than a single one. Most of the infective agents that cause respiratory disease are ubiquitous in the environment and are present as normal residents in the nasal cavities of normal animals. This often creates difficulty with the interpretation of the microbiological findings in outbreaks of respiratory disease because the infectious agents can commonly be isolated from...
both sick and well animals. Thus there may be no well-defined cause-and-effect relationship and the predisposing causes begin to assume major importance in any control program.

**MANAGEMENT TECHNIQUES**

Most of the common respiratory diseases occur at certain times under certain conditions and successful control will depend on the use of management techniques before the disease is likely to occur. For example, in beef cattle, pneumonic pasteurellosis can be kept to a minimum with the use of certain management procedures that minimize stress at weaning. The incidence of pneumonia can be minimized in young bulls destined for a performance testing station during the cold winter months and hot and stuffy during the summer months. Outbreaks of enzootic pneumonia can be minimized in young cattle from several different backgrounds which have been mingled after having been transported long distances. Outbreaks of equine respiratory disease occur in young horses that are assembled at the racetrack for training or at horse shows.

**HOUSING FACILITIES**

Cattle and pig barns that are overcrowded, damp and cold during the cold winter months and hot and stuffy during the summer months can predispose to a high incidence of pneumonia. The morbidty and mortality from pneumonia may be much higher when the ammonia concentration of the air is high or if it is dusty.

The incidence of pulmonary inflammation and coughing (heaves) in horses is much higher in those that are housed in barns that are dusty and not ventilated compared to horses kept outdoors. Bad stable management as a major cause of coughing in horses was described almost 200 years ago but there is still a major emphasis on the clinical management of chronic coughing in housed horses using a wide spectrum of antibiotics, expectorants and other drugs. More consideration of good housing and ventilation is necessary.

In pigs, enzootic pneumonia is widespread but the effects of the pneumonia can be maintained at an insignificant level with adequate housing, ventilation and nutrition. Too much emphasis has been placed on the attempted eradication of *Mycoplasma* spp., which is extremely difficult, and insufficient emphasis on building design and ventilation methods.

**VACCINES**

Vaccines are available for the immunization of farm animals against some of the common infectious diseases of the respiratory tract. Their advantages and disadvantages are discussed under each specific disease. The general principles underlying use of vaccines for control of respiratory disease are that:

- The disease must be caused by a disease that is infectious
- There must be an effective vaccine suitable for use in the species and age group of animals at most risk of the disease. Ideally, this will be known from published, appropriately designed trials testing the vaccine in a group of animals identical to those in which the vaccine will be used in practice
- The vaccine must be administered to animals in such a manner (route, timing, frequency) as to optimize the immunization (adaptive immunity)
- The timing of the vaccination program should be such that maximal resistance to the anticipated diseases is achieved at the time of greatest risk of the disease
- Vaccination should be part of an ongoing program of disease control and should not be regarded as a panacea with which to rectify other shortcomings in management of the animals.

**ENVIRONMENTAL CONTROL**

In effect, the principles of control and prevention of airborne respiratory disease are based largely on keeping the levels of pathogens in the air at a low level. This can be accomplished by a combination of the following practices:

- The use of filtered-air positive pressure ventilation systems
- The removal of affected animals from the group
- Increasing the ventilation rate of the building unit
- Subdivision of the unit into small units, each with its own ventilation system
- A continual disinfection system where appropriate and practicable
- The provision of supplemental heat so that during cold weather the ventilation can be maintained and animals will not huddle together to keep warm and thereby increase the exposure rate of infection
- The use of vaccines for specific diseases of the respiratory tract
- Effective dust control.

PULMONARY CONGESTION AND EDEMA

Pulmonary congestion is caused by an increase in the amount of blood in the lungs due to engorgement of the pulmonary vascular bed. It is sometimes followed by pulmonary edema when intra-vascular fluid escapes into the parenchyma and alveoli. The various stages of the vascular disturbance are characterized by respiratory compromise, the degree depending upon the amount of alveolar air space which is lost.

ETIOLOGY

Pulmonary congestion and edema is a common terminal event in many diseases depending upon the amount of alveolar air space which is lost. Pulmonary edema occurs because of imbalances in the Starling forces across the pulmonary capillary. From a clinical perspective, the common proximate causes of pulmonary edema are injury to the endothelium of the pulmonary capillary with subsequent leakage of protein-rich fluid into the interstitial spaces, elevated blood pressure in the alveolar capillaries, or low plasma oncotic pressure. Damage to pulmonary vascular endothelium can occur in infectious diseases (e.g. African horse sickness) or intoxications (endotoxemia). Physical injury, including inhalation of excessively hot air or smoke, can damage the alveolar epithelium with secondary damage to capillary endothelium. Elevated pulmonary capillary pressure occurs in left-sided heart failure (ruptured chordae tendineae of the mitral valve) and during strenuous exercise by horses. Low plasma oncotic pressure occurs in diseases causing hypoproteinemia but is rarely a cause for pulmonary edema by itself, although it contributes to the pulmonary edema in hypoproteinemic animals administered large volumes of fluids intravenously.

Primary pulmonary congestion
- Early stages of most cases of pneumonia
- Inhalation of smoke and fumes
- Anaphylactic reactions
- Hypostasis in recumbent animals
- Yew (Taxus sp.) intoxication
- Race horses with acute severe exercise-induced pulmonary hemorrhage

Secondary pulmonary congestion
- Congestive heart failure (cardiogenic pulmonary edema), including ruptured chordae tendineae of the mitral valve, and left-sided heart failure.

Pulmonary edema
Pulmonary edema as a sequel to pulmonary capillary hypertension or pulmonary microvascular damage occurs in:
- Acute anaphylaxis
- Acute pneumonia – Pasteurella haemolytica produces several virulence factors that induce direct or leukocyte-mediated pulmonary endothelial cell injury
- Gram-negative sepsis in ruminants and pigs
- Congestive heart failure and acute heart failure, e.g. the myocardial form of enzootic muscular dystrophy in inherited myocardiopathy of Hereford calves; ruptured mitral valve or chordae tendineae
- Inhalation of smoke or manure gas
- Transient upper airway obstruction in the horse (negative pressure pulmonary edema)
- After general anesthesia in horses

Diseases of the lungs

PART 1 GENERAL MEDICINE   Chapter 10: Diseases of the respiratory system
In anoxia develops and is the cause of most reduced and oxygenation of the blood is impaired. Oxygenation is reduced by the decreased rate of blood flow through the pulmonary capillaries. Filling of the alveoli, and in severe cases the bronchi, effectively prevents gaseous exchange.

Smoke inhalation in horses results in decreased oxygen content of inspired air and exposure of the respiratory tract tissues to various noxious gases. Following smoke inhalation, diffuse tracheobronchial mucosal sloughing occurs, which, if progressive, causes separation of the epithelium and development of pseudomembranous casts, which may cause partial or complete airway obstruction. Pulmonary edema is also extensive.

Clinical Findings
All degrees of severity of pulmonary congestion and edema occur commonly in farm animals and only the most severe form is described here. The depth of respiration is increased to the point of extreme dyspnea with the head extended, the nostrils flared and mouth-breathing. Breathing movements are greatly exaggerated and can be best described as heaving; there is marked abdominal and thoracic movement during inspiration and expiration. A typical stance is usually adopted, with the front legs spread wide apart, the elbows abducted and the head hung low. The respiratory rate is usually increased especially if there is hyperthermia, which occurs in acute anaphylaxis and after violent exercise as well as in the early stages of pneumonia. The heart rate is usually elevated (up to 100/min) and the nasal mucosa is bright red or cyanotic in terminal cases.

In acute pulmonary congestion there are harsh breath sounds but no crackles are present on auscultation.

When pulmonary edema develops, loud breath sounds and crackles are audible over the ventral aspects of the lungs. In long-standing cases there may be emphysema with crackles and wheezes of the dorsal parts of the lungs, especially if the lesion is caused by anaphylaxis.

Coughing is usually present but the cough is soft and moist and is not painful. A slight to moderate serous nasal discharge occurs in the early stage of congestion but in severe pulmonary edema this increases to a voluminous, frothy nasal discharge, which is often pink-colored due to blood.

The primary importance of pulmonary congestion is as an indicator of early pathological changes in the lung or heart. Spontaneous recovery occurs quickly unless there is damage to alveolar epithelium, or myocardial asthenia develops. Severe pulmonary edema has much greater significance and usually indicates a stage of irreversibility. Death in cases of pulmonary edema is accompanied by asphyxial respiratory failure.

Smoke inhalation in horses is characterized by:
- Polypnea and dyspnea
- Diffuse wheezes throughout the lungs
- Coughing
- A bronchointerstitial pattern radiographically
- The horse may expectorate large proteinaceous tracheobronchial casts.

The prognosis is good if affected animals can survive the initial stages of pulmonary damage and secondary organ involvement.

Clinical Pathology
Laboratory examinations are of value only in differentiating the causes of the congestion or edema. Bacteriological examination of nasal swabs and a complete hematological examination, looking particularly for the presence of eosinophilia, are the standard examinations that are carried out.

Necropsy Findings
In acute pulmonary congestion the lungs are dark red in color. Excessive quantities of venous blood exude from the cut surface. Similar but less marked changes occur in milder forms of congestion but are only seen in those animals that die from intercurrent disease. Histologically the pulmonary capillaries are markedly engorged and some transudation and hemorrhage into alveoli is evident.

Macroscopic findings in pulmonary edema include swelling and loss of elasticity of the lungs, which pit on pressure. They are usually paler than normal. Excessive quantities of serous fluid exude from the cut surface of the lung. Histologically there are accumulations of fluid in the alveoli and parenchyma.

Diffuse wheezes throughout the lungs and the nasal mucosa are dark red in color. Excessive quantities of serous proteinaceous tracheobronchial casts are present on auscultation. Diffuse wheezes are present throughout the lungs and the nasal mucosa is bright red or cyanotic in terminal cases.

Excessive quantities of serous fluid exude from the cut surface of the lung. Histologically there are accumulations of fluid in the alveoli and parenchyma.

Differential Diagnosis
The diagnosis of pulmonary congestion and edema is always difficult unless there is a history of a precipitating cause such as an infectious disease, strenuous exercise, ingestion of toxicants, or inhalation of smoke or fumes. Pneumonia usually presents itself as an alternative diagnosis and a decision cannot be based entirely on the presence or absence of pyrexia. The best indication is usually the presence of toxemia but this again is not entirely dependable. Bacterial pneumonia is usually accompanied by some toxemia but cases of viral pneumonia are often free of it. Response to antibacterial treatment is one of the best indications, the only variable being the tendency for congestion and edema of allergic origin to recover spontaneously. In many instances there will be doubt and it is then advisable to treat the animal for both conditions.

Treatment
The principles of treatment of pulmonary congestion and edema are one or more of: reduction of pulmonary capillary pressure (by reduction either of pulmonary venous or pulmonary arterial pressure); alleviation of pulmonary microvascular damage; and correction of low plasma oncotic pressure. The treatment of pulmonary congestion and edema must first be directed at correction of the primary cause as listed under etiology. Affected animals should be confined at rest in a clean, dry environment and exercise avoided.

Pulmonary capillary pressure can be reduced in animals with left-sided heart failure by reduction of cardiac preload, improvement in cardiac pump function or a combination of these factors. These topics are dealt with in detail in Chapter 8. Briefly, preload can be reduced by administration of furosemide and pump function improved by administration of drugs that improve myocardial function (digoxin) or decrease afterload (arterial vasodilators). The usual first step is the
administration of furosemide (1–2 mg/kg intravenously).

Alleviation of pulmonary microvascular damage is more difficult. Administration of anti-inflammatory drugs including NSAIDs or glucocorticoids is indicated in animals in which microvascular damage is suspected. These drugs are used to treat, among other diseases, smoke inhalation of horses.1

Plasma oncotic pressure can be increased by intravenous infusion of plasma (10–40 mL/kg) or synthetic colloids such as hetastarch. Administration of crystalloid solutions should be judicious and the amount of fluid administered must be monitored carefully to ensure that only sufficient fluids to meet the needs of the animal are given.

Oxygen should be administered to hypoxicemic animals in conjunction with other specific treatments.

Special diseases
When edema is due to organophosphate poisoning prompt administration of atropine may reduce fluid transudation. In these cases the animal is in considerable danger and repeated injections may be necessary. Details of the recommended treatment regimen are given in the section on treatment of poisoning by organophosphorus compounds.

Epinephrine is recommended in pulmonary edema due to anaphylaxis. It will have an immediate pharmacological effect, which may be followed by the use of a corticosteroid to maintain vascular integrity and to decrease permeability of pulmonary vessels. Antihistamines are commonly used in conjunction with epinephrine for the treatment of acute pulmonary edema due to anaphylaxis. However, recent studies of experimental anaphylaxis in cattle and horses have shown that the antihistamines may be of limited value because histamine and serotonin are of relatively limited significance as mediating substances. On the other hand, the kinins, prostaglandins and slow-release substances may be more important.

Studies in cattle have found that antihistamines and 5-hydroxytryptamine (5-HT) antagonists failed to protect cattle in experimental hypersensitivity. Sodium meclofenamate has been more successful in antagonizing experimental anaphylaxis in cattle and horses. Acetylsalicylic acid was more effective than antihistamines or antiserotonin agents in providing symptomatic relief in experimental acute interstitial pneumonia of calves.

It is difficult, however, to extrapolate the results of these studies in which the drugs were usually given before or at the same time as the experimental disease was produced. There is a need for development of more effective antianaphylactic drugs for the treatment of acute anaphylaxis in farm animals, which invariably results in pulmonary edema and emphysema. Thus epinephrine is the drug of choice for the emergency treatment of pulmonary edema due to anaphylaxis.

PULMONARY HYPERTENSION
Pulmonary hypertension is an increase in pulmonary arterial pressure above normal values due to structural or functional changes in the pulmonary vasculature. Primary pulmonary hypertension occurs in cattle with high-altitude disease. Chronic pulmonary hypertension results in right-side congestive heart failure due to right ventricular hypertrophy or cor pulmonale.

Causes
Hypoxemia is a potent stimulus of pulmonary arterial pressure through increased pulmonary vascular resistance induced by pulmonary vasosconstriction.1 Pulmonary artery pressure can also increase in response to increases in cardiac output that are not matched by pulmonary vasodilation—the most extreme example of this being the large increase in pulmonary arterial pressure of strenuously exercising horses. Alveolar hypoxia causes constriction of the precapillary pulmonary vessels, resulting in pulmonary hypertension. Conditions which may induce hypoxia include:
- Exposure to high altitude
- Respiratory impairment secondary to thoracic wall abnormalities
- Airway obstruction
- Pneumonia
- Pulmonary edema
- Emphysema
- Pulmonary vascular disease
- Heaves

At high altitudes, the low inspired oxygen tension causes hypoxic pulmonary vasoconstriction and hypertension that are common causes of cor pulmonale (brisket disease) in cattle. Susceptible cattle can be identified by measurement of pulmonary artery pressure before clinical disease develops. This test is used to select bulls for use in high-altitude pastures. Cattle grazing pastures that contain locoweed have an increased incidence of brisket disease but the pathogenesis is unknown. Although uncommon, right-sided congestive heart failure and pulmonary hypertension can occur in cows at low altitudes with primary lung disease.1

Pulmonary hypertension occurs in neonates and is a consequence of persistent fetal circulation (see Ch. 8). This is particularly a problem of cloned calves.2

An outbreak of pulmonary hypertension in a group of dairy calves 5–6 months of age has been described.3 Some affected calves died suddenly. Clinical findings included lethargy, anorexia, pale mucous membranes, tachypnea, tachycardia, weakness, engorged jugular veins and loss of body condition.4 Right-side cardiac catheterization revealed pulmonary hypertension. Necropsy findings revealed evidence of right-sided congestive heart failure, and periarthritis and fibrosis of the pulmonary and bronchial arteries. Lesions were characterized by variable stages of vasculitis; the airways were free of pathological changes. Ingestion of monocrotaline, a pyrrolizidine alkaloid, can cause similar pulmonary vascular lesions in rats but no evidence of such ingestion was found in affected calves.

Pulmonary hypertension occurs secondary to left-sided heart disease in horses, although the hypertension has been mistakenly identified as the primary lesion.4

ATELECTASIS
Atelectasis is collapse of the alveoli due to failure of the alveoli to inflate or because of compression of the alveoli. Atelectasis is therefore classified as obstruction (resorption), compression or contraction. Obstruction atelectasis occurs secondary to obstruction of the airways, with subsequent resorption of alveolar gases and collapse of the alveoli. This disease is usually caused by obstruction of small bronchioles by fluid and exudate. It is common in animals with pneumonia or aspiration of a foreign body. Compression atelectasis occurs when intrathoracic (intrapleural) pressure exceeds alveolar pressure, thereby deflating alveoli. This occurs when there is excessive pleural fluid or the animal has a pneumothorax. In large animals it also occurs in the dependent lung or portions of lung in recumbent animals. Compression
atelectasis is the explanation for the large shunt fraction and hypoxemia that occurs in anesthetized horses.\textsuperscript{1} Compression atelectasis and secondary bronchopneumonia can occur in horses kept in flotation tanks for up to several weeks for treatment of skeletal injuries.\textsuperscript{2} Contraction atelectasis occurs when there is compression of parts of the lung by fibrotic changes in the pleura. Patchy atelectasis occurs in the absence of surfactant, such as can occur in newborns. Failure of the lung to inflate, or development of atelectasis of the lungs of the newborn, usually those born prematurely, occurs because of lack of pulmonary surfactant. The disorder can progress to hyaline membrane disease. Affected newborn animals are severely dyspneic, hypoxemic, cyanotic, weak and commonly die in a few hours.

The clinical signs of atelectasis are not apparent until there is extensive involvement of the lungs. Animals develop respiratory distress, tachypnea, tachycardia and cyanosis. Blood gas analysis reveals hypoxemia, with or without hypercapnia. Thoracic radiographs reveal pulmonary consolidation. Ultrasonographic examination of the thorax demonstrates consolidated lung.

Atelectasis is reversible if the primary obstruction or compression is relieved quickly before secondary consolidation and fibrosis occur.

ACUTE RESPIRATORY DISTRESS SYNDROME

This is a well-recognized clinical syndrome of humans characterized by acute onset of hypoxemia and pulmonary infiltrates without increases in left atrial pressure (i.e. without evidence of cardiogenic pulmonary edema). Precipitating causes include both direct and indirect lung injury, including sepsis, multiple transfusions, trauma, near-drowning, smoke inhalation, pancreatitis and more. The underlying lesion is diffuse alveolar capillary damage with secondary severe pulmonary edema. The disease occurs spontaneously in domestic animals\textsuperscript{1} and, although the spontaneous disease is not extensively documented, the disease produced experimentally as a model of the human disease is better described.\textsuperscript{2}

Acute respiratory distress syndrome (ARDS) in animals occurs in newborns and in adult animals. The disease in some newborn farm animals is related to lack of surfactant but except for animals born prematurely this is more the exception than the rule. Most young animals and all adult animals with ARDS have some inciting acute lung injury that then progresses to ARDS.\textsuperscript{1,3,4} The causes can be infectious (e.g. influenza virus infection), physical (smoke inhalation) or toxic (endotoxin).

The pathophysiology of the disease involves a common final pathway that results in damage to alveolar capillaries. The initial injury can be to either the endothelium of pulmonary capillaries or to alveolar epithelium. Damage to these structures leads to extravasation of protein-rich fluid and fibrin with subsequent deposition of hyaline membranes. The capillary injury is attributed to activated leukocytes (macrophages and neutrophils) and cytokines. Accumulation of hyaline membranes and ventilation/perfusion mismatches impair respiratory gas exchange and cause hypoxemia.

The clinical signs are characteristic of acute, progressive pneumonia. Animals are anxious, tachycardic, tachypneic and have crackles and wheezes on thoracic auscultation. Severely affected animals can be cyanotic. Thoracic radiographs reveal diffuse pulmonary infiltrates. Hematologic changes are characteristic of the inciting disease but usually include leukopenia. There is arterial hypoxemia.

Treatment includes administration of anti-inflammatory drugs (NSAIDs with or without glucocorticoids), colloids, antimicrobials and oxygen. The arterial blood gas response to oxygen therapy is often minimal in severely affected animals. If it is available, mechanical ventilation can be useful, although the prognosis is grave. Inhalation of nitric oxide is beneficial in some humans with the disease, and there are anecdotal reports that it has been used to treat foals with ARDS.

PULMONARY HEMORRHAGE

Pulmonary hemorrhage is uncommon in farm animals but does occur occasionally in cattle, and exercise-induced pulmonary hemorrhage (EIPH) occurs in 45-75% of exercised horses. Pulmonary hemorrhage also occurs in horses with pulmonary abscesses, tumors or foreign bodies. Tracheobronchoscopic, radiographic and ultrasonographic examinations are useful in identifying the site and cause of the hemorrhage.

Cattle
In cattle the most common cause is erosion of pulmonary vessels adjacent to lesions of embolic pneumonia associated with vena caval thrombosis and hepatic abscessation. The onset of hemorrhage may be sudden and affected animals hemorrhage profusely and die after a short course of less than 1 hour. Marked epistaxis and hemoptysis, severe dyspnea, muscular weakness and pallor of the mucous membranes are characteristic. In other cases, episodes of epistaxis and hemoptysis may occur over a period of several days or a few weeks along with a history of dyspnea.

EXERCISE-INDUCED PULMONARY HEMORRHAGE OF HORSES (EIPH, BLEEDERS)

SYNDROMES

Etiology
Pulmonary hemorrhage during exercise
Epidemiology
Present in most (>80%) Thoroughbred and Standardbred racehorses, although clinical signs are less common. Occurs worldwide in any horse that performs strenuous exercise. Rarely causes death.

Pathogenesis
Probably associated with rupture of pulmonary capillaries by the high pulmonary vascular pressures generated during exercise. There may be a contributory role for inflammation and obstruction of small airways, and tissue damage caused by large and rapid changes in intrathoracic pressure.

Clinical signs
Epistaxis is an uncommon but very specific sign of EIPH in horses that have just exercised. Affected horses may cough or suddenly slow during a race. Endoscopic examination of the trachea and bronchi reveals blood.

Clinical pathology
Presence of hemosiderin-laden macrophages in tracheal aspirates or bronchial lavage fluid.

Lesions
Fibrosis and discoloration of the caudodorsal regions of the lungs. Fibrosis, accumulation of hemosiderin-laden macrophages in interstitial tissue, inflammation and bronchial artery angiogenesis. Horses dying acutely have blood-filled airways and heavy, wet lungs.

Diagnostic confirmation
Demonstration of blood in the trachea or bronchi by endoscopic examination, or cytological examination of tracheal aspirates or bronchoalveolar lavage fluid.

Treatment
None of demonstrated efficacy. Furosemide is used as prophylaxis.

Control
There are no specific control measures, however, prevention of environmental and infectious respiratory disease may reduce the incidence of the disease.

Etiology
EIPH is primarily a disease of horses, although it has been reported in racing camels.\textsuperscript{1} EIPH occurs in horses worldwide...
and there does not appear to be any geographical distribution. It is a disorder of horses that run at high speed, such as Thoroughbred or Standardbred racehorses. The disorder is uncommon in endurance horses or draft breeds, although it does occur in horses used for these activities. As a general rule, the more intense the exercise or the higher the speed attained, the greater the proportion of horses with EIPH.

The prevalence of EIPH varies with the method used to detect it and the frequency with which horses are examined, as discussed later in this section. Epistaxis associated with exercise is almost always attributable to pulmonary hemorrhage and occurs only in a small proportion of racehorses. Epistaxis occurs in only 3% of horses that have blood detected in the trachea by endoscopic examination performed within 2 hours of racing. The prevalence of epistaxis in racehorses varies between 0.1 and 9.0%, with the frequency depending on the breed, age and sex of horses selected for study, the type of racing and the timing and frequency of observation of horses after racing. Epistaxis is more common in older horses. There are conflicting reports of a sex predisposition, although epistaxis may be more common in female Thoroughbreds. Epistaxis is more common after races of greater than 1600 m than in longer races, although not all sources agree on this point. However, horses in steeplechase races, which are typically longer than 2000 m, are at greater risk of epistaxis than are horses in flat races. Epistaxis is relatively uncommon and most horses with EIPH do not have epistaxis.

There are a variety of other methods of detecting EIPH, including endoscopic examination of the airways and microscopic examination of tracheal aspirates or bronchoalveolar lavage fluid. Almost all Thoroughbred racehorses in active training have hemosiderophages in bronchoalveolar lavage fluid, indicating that all have some degree of EIPH. The prevalence of EIPH decreases when diagnosis is based on endoscopic examination of horses after exercise or racing.

Exercise-induced pulmonary hemorrhage is very common in Thoroughbred racehorses, with estimates of prevalence, based on a single endoscopic examination of the trachea and bronchi, of 43–75%. The prevalence increases with the frequency of examination, with over 80% of horses having evidence of EIPH on at least one occasion after examination after each of three consecutive races. The prevalence of EIPH in Standardbred racehorses is assumed to be lower, with 26–34% of horses reported to have blood in the trachea after racing. However, these studies were based on a single examination and one only reported as positive those horses with blood covering more than one half the tracheobronchial tree. When examined after each of three races, 87% of Standardbred racehorses have evidence of EIPH on at least one occasion, suggesting that EIPH is as common in Standardbred racehorses as it is in Thoroughbred racehorses.

Exercise-induced pulmonary hemorrhage occurs in approximately 62% of racing Quarter horses, and has been observed in Quarter horses used for barrel racing. The disorder occurs in racing Appaloosa horses. Approximately 11% of polo ponies are affected with EIPH. The disease occurs in draft horses but is not well documented.

Age is considered a risk factor for EIPH, with the prevalence of the disorder being higher in older horses. There is no consistent association of sex with prevalence of EIPH. Among Thoroughbred racehorses the prevalence of EIPH increases with increasing speed, being greater in Thoroughbreds after racing than after breeding (galloping). Lesions of EIPH are not detected in young Thoroughbred racehorses that have trained at speeds of less than 7 m/s.

Pathogenesis

The cause of EIPH is rupture of alveolar capillary membranes with subsequent extravasation of blood into interstitial and alveolar spaces. The source of blood in such instances is the pulmonary circulation. Bleeding from bronchial circulation during exercise has been suggested, based on histological evidence of bronchial angiogenesis in horses that have experienced previous episodes of EIPH, but contribution of the bronchial circulation to EIPH has not been demonstrated. Regardless of the contribution of bronchial circulation to blood in the airways, the likely initial lesion is in capillaries associated with the pulmonary circulation. Hemorrhage into the interstitial space and alveoli, with subsequent rostral movement of blood in the airways, results in blood in the trachea and bronchi.

Rupture of alveolar capillaries occurs secondary to an exercise-induced increase in transmural pressure (pressure difference between the inside of the capillary and the alveolar lumen). If the transmural stress exceeds the tensile strength of the capillary wall, the capillary ruptures. The proximate cause of alveolar capillary rupture is the high transmural pressure generated by positive intracapillary pressures, which are largely attributable to capillary blood pressure, and the lower intra-alveolar pressure generated by the negative pleural pressures associated with inspiration.

During exercise, the absolute magnitudes of both pulmonary capillary pressure and alveolar pressure increase, with a consequent increase in transmural pressure. Strenuous exercise is associated with marked increases in pulmonary artery pressure in horses. Values for mean pulmonary arterial pressure at rest of 20–25 mmHg increase to more than 90 mmHg during intense exercise because of the large cardiac output achieved by exercising horses. The increases in pulmonary artery pressure, combined with an increase in left atrial pressure during exercise, probably result in an increase in pulmonary capillary pressure. Combined with the increase in pulmonary capillary pressure, a marked decrease (more negative) in pleural, and therefore alveolar, pressure during exercise. The pleural pressure of normal horses during inspiration decreases from approximately −0.7 kPa (~5.3 mmHg) at rest to as low as −8.5 kPa (64 mmHg) during strenuous exercise. Together, the increase in pulmonary capillary pressure and decrease (more negative) in intrapleural (alveolar) pressure contribute to a marked increase in stress in the alveolar wall. Although the alveolar wall and pulmonary capillaries of horses are stronger than those of other species, rupture may occur because the wall stress in the alveolus exceeds the mechanical strength of the capillary.

Other theories of the pathogenesis of EIPH include: small-airway disease, upper airway obstruction, hemostatic abnormalities, changes in blood viscosity and erythrocyte shape, intrathoracic shear forces associated with gait, and bronchial artery angiogenesis. It is likely that the pathogenesis of EIPH involves several processes, including pulmonary hypertension, lower alveolar pressure and changes in lung structure, that summate to induce stress failure of pulmonary capillaries.

Obstruction of either the upper or lower airways has been proposed as a cause of EIPH. Inspiratory airway obstruction results in more negative intrapleural, and therefore alveolar, pressures. This effect is exacerbated by exercise, with the result that alveolar transmural pressure is greater in horses with airway obstruction. The higher transmural pressure in such horses may increase the severity of EIPH, although this has not been demonstrated. Moreover, while inspiratory airway obstruction may predispose to EIPH, the prevalence of this condition is much less than that of EIPH, indicating that it is not the sole factor inducing EIPH in most horses.
Horses with moderate to severe EIPH have histological evidence of inflammation of the small airways, and there is a clear association between the presence of EIPH and inflammatory changes in bronchoalveolar or tracheal aspirate fluid. However, instillation of autologous blood into the airways induces a marked inflammatory response in normal horses, and it is therefore unclear whether inflammation alone induces or predisposes to EIPH or whether the inflammation is a result of EIPH. Theoretically, small-airway inflammation and bronchoconstriction have the potential to produce intrathoracic airway obstruction and, therefore, a more negative alveolar pressure. Given that small-airway disease is common in horses, there is the potential for an important effect of factors, such as viral infections, air pollution and allergic airway disease, to contribute to the initiation or propagation of EIPH.

The characteristic location of lesions of EIPH in the caudodorsal lung fields has led to the proposal that hemorrhage is a result of tissue damage occurring when waves of stress, generated by forelimb foot strike, are focused and amplified into the narrowing cross-sectional area of the caudal lung lobes. According to the theory, the locomotor impact of the forelimbs is the result of having defects in either hemostasis or fibrinolysis. However, while exercise induces substantial changes in blood coagulation and fibrinolysis, there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.

Regardless of the cause, rupture of pulmonary capillaries and subsequent hemorrhage into airways and interstitium causes inflammation of both airways and interstitium with subsequent development of fibrosis and alteration of tissue compliance. Heterogeneity of compliance within the lungs, and particularly at the junction of normal and diseased tissue, results in the development of abnormal shear stress with subsequent tissue damage. These changes are exacerbated by inflammation and obstruction of small airways, with resulting uneven inflation of the lungs. The structural abnormalities, combined with pulmonary hypertension and the large intrathoracic forces associated with respiration during strenuous exercise, cause repetitive damage at the boundary of normal and diseased tissue with further hemorrhage and inflammation. The process, once started, is lifelong and continues as long as the horse continues to perform strenuous exercise.

**Clinical findings**

Poor athletic performance or epistaxis are the most common presenting complaints for horses with EIPH. While poor performance may be attributable to any of a large number of causes, epistaxis associated with exercise is almost always secondary to EIPH.

Epistaxis due to EIPH occurs during or shortly after exercise and is usually first noticed at the end of a race, particularly when the horse is returned to the paddock or winner's circle and is allowed to lower its head. It is usually bilateral and resolves within hours of the end of the race. Epistaxis may occur on more than one occasion, especially when horses are raced or exercised at high speed soon after an initial episode.

Exercise-induced pulmonary hemorrhage and performance

Failure of racehorses to perform to the expected standard (poor performance) is often, accurately or not, attributed to EIPH. Many horses with poor performance have cytological evidence of EIPH on microscopic examination of tracheobronchial aspirates or bronchoalveolar lavage fluid or have blood evident on endoscopic examination of the tracheobronchial tree performed 30–90 minutes after strenuous exercise or racing. However, it is important to recognize that EIPH is very common in racehorses and it should be considered the cause of poor performance only after other causes have been eliminated. Severe EIPH undoubtedly results in poor performance and, on rare occasions, death of Thoroughbred racehorses.

Thoroughbred horses with EIPH racing in Victoria, Australia have impaired performance compared to unaffected horses. Affected horses have a lower likelihood of finishing in the first three places, are less likely to be elite money earners and finish further behind the winner than do unaffected horses.

Results of studies in Standardbred racehorses indicate either a lack of effect of EIPH on performance or an association between EIPH and superior performance. There was no relationship between presence of EIPH and finishing position in 29 Standardbred racehorses with intermittent EIPH examined on at least two occasions, nor in 92 Standardbred racehorses examined on one occasion. However, of 965 Standardbred racehorses examined after racing, those finishing first or second were 1.4 times more likely (95% confidence interval 0.9–2.2) to have evidence of EIPH on tracheobronchoscopic examination than were horses that finished in seventh or eighth position.

**Physical examination**

Apart from epistaxis in a small proportion of affected horses, there are few abnormalities detectable on routine physical examination of horses with EIPH. Rectal temperature and heart and breathing rates may be elevated as a consequence of exercise in horses examined soon after exercise, but values of these variables in horses with EIPH at rest are not noticeably different from horses with no evidence of EIPH. Affected horses may swallow more frequently during recovery from exercise than do unaffected horses, probably as a result of blood in the larynx and pharynx. Coughing is common in horses recovering from strenuous exercise and after recovery from exercise; horses with EIPH are no more likely to cough than are unaffected horses. Other clinical signs related to respiratory abnormalities are uncommon in horses with EIPH. Respiratory distress is rare in horses with EIPH and, when present, indicates severe hemorrhage or other serious lung disease such as pneumonia, pneumothorax or rupture of a pulmonary abscess. Lung sounds are abnormal in a small number of EIPH-affected horses and when present are characterized by increased intensity of normal breath sounds during rebreathing examination. Tracheal rales may be present in horses with EIPH but are also heard in unaffected horses.

**Tracheobronchoscopy**

Observation of blood in the trachea or large bronchi of horses 30–120 minutes after racing or strenuous exercise provides a definitive diagnosis of EIPH. The amount of blood in the large airways varies from a few small specks on the airway walls to a stream of blood occupying the ventral one-third of the trachea. Blood may also be present in the larynx and nasopharynx. If there is a strong suspicion of EIPH and blood is not present on a single examination conducted soon after exercise, the examination should be repeated in 60–90 minutes. Some horses with EIPH do not have blood present in the rostral airways immediately after exercise, but do so when examined 1–2 hours later. Blood is detectable by tracheobronchoscopic examination for 1–3 days in most horses, with some horses having blood detectable for up to 7 days.
Bronchoscopic examination can be used to estimate the severity of EIPH through the use of a grading system. The interobserver repeatability of tracheobronchoscopic assessment of severity of EIPH using a 0–4 grading scale is excellent.

- Grade 0: No blood detected in the pharynx, larynx, trachea or main stem bronchi.
- Grade 1: Presence of one or more flecks of blood or ≤ 2 short (≤ quarter the length of the trachea) narrow (< 10% of the tracheal surface area) streams of blood in the trachea or main stem bronchi visible from the tracheal bifurcation.
- Grade 2: One long stream of blood (> half the length of the trachea) or > 2 short streams occupying less than one-third of the tracheal circumference.
- Grade 3: Multiple, distinct streams of blood covering more than one-third of the tracheal circumference. No blood pooling at the thoracic inlet.
- Grade 4: Multiple, coalescing streams of blood covering > 90% of the tracheal surface with pooling of blood at the thoracic inlet.

It is assumed that a higher score represents more severe hemorrhage, but while the repeatability of this scoring system has been established, the relationship between the amount of blood in the large airways and the actual amount of hemorrhage has not been established.

Radiography
Thoracic radiography is of limited use in detecting horses with EIPH. Radiographs may demonstrate the presence of densities in the caudodorsal lung fields of some horses but many affected horses have minimal to undetectable radiographic abnormalities. Examination of thoracic radiographs of horses with EIPH may be useful in ruling out the presence of another disease process, such as a pulmonary abscess, contributing to the horse's pulmonary hemorrhage or poor athletic performance.

Prognosis
Horses that have experienced one episode of epistaxis are more likely to have a second episode. For this reason, most racing jurisdictions do not permit horses with epistaxis to race for a period of weeks to months after the initial instance, with more prolonged enforced rest after a subsequent episode of epistaxis and retirement from racing after a third bout. The recurrence rate after one episode of epistaxis in Thoroughbred horses is approximately 13.5% despite affected horses not being permitted to race for 1 month after the initial episode. This high rate of recurrence suggests that the inciting pulmonary lesions have not healed.

Clinical pathology
Examination of airway secretions or lavage fluid
The presence of red cells or macrophages containing either whole red cells or the breakdown products of hemoglobin (hemosiderophages) in tracheal or bronchoalveolar lavage fluid provides evidence of EIPH. Detection of red cells or hemosiderophages in tracheal aspirates or bronchoalveolar lavage fluid is believed to be both sensitive and specific in the diagnosis of EIPH. Examination of airway fluids indicates the presence of EIPH in a greater proportion of horses than does tracheobronchoscopic examination after strenuous exercise or racing. The greater sensitivity of examination of airway fluid is probably attributable to the ability of this examination to detect the presence of small amounts of blood or its residual products and the longevity of these products in the airways. While endoscopic examination may detect blood in occasional horses up to 7 days after an episode of EIPH, cellular evidence of pulmonary hemorrhage persists for weeks after a single episode. Red blood cells and macrophages containing red cells are present in bronchoalveolar lavage fluid or tracheal aspirates for at least 1 week after strenuous exercise or instillation of autologous blood into airways and hemosiderophages are present for at least 21 days and possibly longer.

Recent studies have reported on the use of red cell numbers in bronchoalveolar lavage fluid as a quantitative indicator of EIPH. However, this indicator of EIPH severity has not been validated nor demonstrated to be more reliable or repeatable than tracheobronchoscopic examination and visual scoring. Furthermore, considerable concern exists over the suitability of red cell counts in bronchoalveolar lavage fluid for assessment of severity of EIPH given that an unknown area, although presumably small, of the lung is examined by lavage and that there is a risk that this area of lung may not be representative of the lung as a whole, similar to the situation of examination of bronchoalveolar lavage fluid of horses with pneumonia. Bronchoalveolar lavage of sections of both lungs, achieved using an endoscope, may obviate some of these concerns.

Tracheal aspirates may be obtained any time after exercise by aspiration either during tracheobronchoscopic examination or through a percutaneous intratracheal needle. Aspirates obtained through an endoscope may not be sterile, depending on the collection technique. Bronchoalveolar lavage fluid can be obtained through either an endoscope wedged in the distal airway or a cuffed tube inserted blindly into a distal airway. Collection of fluid through an endoscope has the advantage of permitting examination of the distal airways and selection of the area of lung to be lavaged. However, it does require the use of an endoscope that is longer (2 m) than those readily available in most equine practices. Use of a commercial bronchoalveolar lavage catheter does not require use of an endoscope and this procedure can be readily performed in field situations.

Differential Diagnosis
Epistaxis and hemorrhage into airways can occur as a result of a number of diseases (Table 10.5).

Necropsy
Exercise-induced pulmonary hemorrhage is a rare cause of death of racehorses, but among race horses that die during racing for reasons other than musculoskeletal injuries, EIPH is common. Necropsy examination of horses is usually incidental to examination for another cause of death. Pertinent abnormalities in horses with EIPH are restricted to the respiratory tract. Grossly, horses examined within hours of strenuous exercise, such as horses examined because of catastrophic musculoskeletal injuries incurred during racing, may have severe petechiation in the caudodorsal lung fields. Horses with chronic disease have bluish-gray or blue/brown discoloration of the visceral pleural surfaces of the caudodorsal lung fields that is often sharply demarcated, especially on the diaphragmatic surface. The discoloration affects both lungs equally with 30–50% of the lung fields being discolored in severe cases. Affected areas do not collapse to the same extent as unaffected areas and, in the deflated lung, have a spleen-like consistency. On cut surface, the discolored areas of lung are predominantly contiguous with the dorsal pleural surface and extend ventrally into the lung parenchyma. Areas of affected lung may be separated by normal lung. There is proliferation of bronchial vessels, predominantly arteries and arterioles, in affected areas. Histologically, affected areas exhibit bronchiolitis, hemosiderophages in the alveolar lumen and interstitial spaces, and fibrosis of interlobular septa, pleural and around vessels and bronchioles.

Treatment

Reducing pulmonary capillary pressure
Furosemide administration as prophylaxis of EIPH is permitted in a number of racing jurisdictions worldwide, most notably Canada, the USA, Mexico and most of the South American countries. Within the USA and Canada, almost all Thoroughbred, Standardbred and Quarter horse racing jurisdictions permit administration of furosemide before racing.

The efficacy of furosemide in treatment of EIPH is uncertain. While field studies of large numbers of horses do not demonstrate an effect of furosemide on the severity of EIPH, studies of Thoroughbred horses running on a treadmill provide evidence that furosemide reduces the severity of EIPH. Under field conditions, based on tracheobronchoscopic evaluation of the severity of bleeding, furosemide has been reported to reduce or have no influence on the severity of bleeding. This apparent inconsistency may be attributable to measurement of red blood cell counts in bronchoalveolar lavage fluid of horses that have run on a treadmill not being representative of effects of furosemide under field conditions. The weight of evidence, albeit unconvincing, from field studies does not support a role for furosemide in preventing or reducing the severity of EIPH.

The mechanism by which furosemide may reduce the severity of EIPH is unknown, although it is speculated that furosemide, by attenuating the exercise-induced increase in pulmonary artery and pulmonary capillary pressure of horses, reduces the frequency or severity of pulmonary capillary rupture.

Furosemide is associated with superior performance in both Thoroughbred and Standardbred racehorses, which further complicates assessment of its efficacy in treating EIPH.

An increase in pulmonary capillary pressure secondary to altered rheostatic properties of blood during exercise has been suggested as a possible contributing factor for EIPH.

Increasing alveolar inspiratory pressure
Airway obstruction, either intrathoracic or extrathoracic, increases airway resistance and results in a more negative intrathoracic (pleural) pressure during inspiration to maintain tidal volume and alveolar ventilation. Causes of extrathoracic airway obstruction include laryngeal hemiplegia

</table>

The table lists the causes of epistaxis and their respective signs and diagnosis, treatment, and control measures. The table is a summary of the information provided in the text, with the addition of a column for treatment and control measures.
The use of bedding of low allergenic potential (shredded paper) to prevent EIPH has no apparent effect on prevalence of the condition. While it is suggested that preventing or minimizing small-airway disease may reduce the severity of EIPH, studies to demonstrate such an effect have not been reported. However, optimizing the air quality in barns and stables and preventing infectious respiratory disease appear sensible precautions.

Interstitial inflammation and bronchial angiogenesis

Hemorrhage into interstitial tissues induces inflammation with subsequent development of fibrosis and bronchial artery angiogenesis. The role of these changes in perpetuating EIPH in horses is unclear but is probably of some importance. Treatments to reduce inflammation and promote healing with minimal fibrosis have been proposed. Rest is an obvious recommendation and many racing jurisdictions have rules regarding enforced rest for horses with epistaxis. While the recommendation for rest is intuitive, there is no information that rest reduces the severity or incidence of EIPH in horses with prior evidence of this disorder.

Similarly, corticosteroids are often administered, either by inhalation, enterally or parenterally, in an attempt to reduce pulmonary inflammation and minimize fibrosis. Again, the efficacy of this intervention in preventing or minimizing severity of EIPH has not been documented.

Excessive bleeding

Coagulopathy and fibrinolysis

Exercise induces substantial changes in blood coagulation and fibrinolysis. However, there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis. Regardless, aminocaproic acid, a potent inhibitor of fibrin degradation, has been administered to horses to prevent EIPH. The efficacy of aminocaproic acid in preventing EIPH has not been demonstrated. Similarly, estrogenic drugs are given to horses with the expectation of improving hemostasis, although the effect of estrogen on coagulation in any species is unclear. There is no evidence that estrogen prevents EIPH in horses.

Vitamin K is administered to horses with EIPH, presumably in the expectation that it will decrease coagulation times. However, as EIPH is not associated with prolonged bleeding times, it is unlikely that this intervention will affect the prevalence or severity of EIPH.

Platelet function

Aspirin inhibits platelet aggregation in horses and increases bleeding time. Seemingly paradoxically, aspirin is sometimes administered to horses with EIPH because of concerns that increased platelet aggregation contributes to EIPH. There is no evidence that aspirin either exacerbates or prevents EIPH.

Capillary integrity

Capillary fragility increases the risk of hemorrhage in many species. Various bioflavonoids have been suggested to increase capillary integrity and prevent bleeding. However, hesperidin and citrus bioflavonoids have no efficacy in prevention of EIPH in horses. Similarly, vitamin C is administered to horses with EIPH without scientific evidence of any beneficial effect.

Summary of treatment options

Selection of therapy for horses with EIPH is problematic. Given that most horses have some degree of pulmonary hemorrhage during most bouts of intense exercise, the decision must be made not only as to the type of treatment and its timing but also which horses to treat. Moreover, the apparently progressive nature of the disease with continued work highlights the importance of early and effective prophylaxis and emphasizes the need for studies of factors such as air quality and respiratory infections in inciting the disorder.

The currently favored treatment for EIPH is administration of furosemide before intense exercise. Its use is permitted in racehorses in a number of countries. Increasingly persuasive laboratory evidence of an effect of furosemide in reducing red cell count in bronchoalveolar lavage fluid collected from horses soon after intense exercise supports the contention that furosemide is effective in reducing the severity of EIPH in racehorses. However, it should be borne in mind that neither the relationship between severity of EIPH and red cell count in bronchoalveolar lavage fluid nor the efficacy of furosemide in reducing severity of EIPH in racehorses in the field has been demonstrated. In fact, there is evidence that furosemide does not reduce the prevalence of EIPH and other evidence that it does not reduce the severity of EIPH under field conditions. The association between furosemide administration and superior performance in Standardbred and Thoroughbred racehorses should be borne in mind when recommending use of this drug.

Prevention and control

There are no documented preventive strategies. Rest is an obvious recommendation for horses with EIPH, but the hemorrhage is likely to recur when the horse is next strenuously exercised.
The duration of rest and the optimal exercise program to return horses to racing after EIPH is unknown, although some jurisdictions require exercise no more intense than trotting for 2 months. Firm recommendations cannot be made on duration of rest because of a lack of objective information.

Although a role for lower airway disease (either infectious or allergic) in the genesis of EIPH has not been demonstrated, control of infectious diseases and minimization of noninfectious lower airway inflammation appears prudent.

Concern about the role of impact waves in the genesis of EIPH has led to discussion of ‘low-stress’ training protocols, but these have not been adequately evaluated.

PULMONARY EMPHYSEMA

Pulmonary emphysema is distension of the lung caused by overdistension of alveoli with rupture of alveolar walls with or without escape of air into the interstitial spaces. Overinflation describes the situation in which there is enlargement of airspaces without tissue destruction. Pulmonary emphysema is always secondary to some primary lesion which effectively traps an excessive amount of air in the alveoli. It is a common clinicopathological finding in many diseases of the lungs of all species and is characterized clinically by dyspnea, hyperpnea, poor exercise tolerance and forced expiration.

ETIOLOGY

Pulmonary emphysema is an important lesion only in cattle, although occasional cases occur in pigs. The bovine lung is highly susceptible to the development of emphysema from many different causes, not all of them respiratory in origin. In those of respiratory origin it is common to find pulmonary emphysema when the primary lesion in the lung causes trapping of air in alveoli or terminal bronchioles. Endotoxemia, for example, can result in diffuse alveolar damage associated with thrombomangitis resulting in pulmonary edema and emphysema. Some causes of emphysema are as follows:

Cattle
- Acute interstitial pneumonia
- Parasitic pneumonia with pulmonary edema in acute anaphylaxis
- Perforation of the lung by foreign body as in traumatic reticuloperitonitis
- Poisoning by the plants Senecio quadridenatus, rape, Zizia arborescens, Perilla frutescens and the fungus Periconia spp. are recorded as causing pulmonary emphysema in cattle
- Pulmonary abscess.

Horses
- Bronchiolitis due to viral infection of the respiratory tract in young horses.

All species
- Secondary to bronchopneumonia
- Poisoning by oleander, Bryophyllum pinnatum and moldy sweet potatoes.
- Acute chemical injury – as in inhalation of welding fumes
- Chlorine gas poisoning
- Local or perifocal emphysema is also a common necropsy finding around local pulmonary lesions, especially atelectasis, often with no respiratory dysfunction. In calves and pigs the emphysema is sometimes sufficiently extensive to kill the animal.

PATHOGENESIS

Emphysema occurs because of destruction of the connective tissues of the lung, including the supporting and elastic tissue of the pulmonary parenchyma. Tissue damage resulting in emphysema in humans is caused by the action of proteases in the lung. Whether this occurs in the farm animal species is unknown but is a consideration. An initial lesion probably leads to an area of weakness from which emphysema spreads during coughing or exertion. In interstitial emphysema there is the additional factor of distension of the connective tissue with air and compression collapse of the alveoli.

The development of interstitial emphysema depends largely upon the amount of interstitial tissue that is present and is most common in cattle and pigs. Whether there is simple overdistension of alveoli or whether their walls are also ruptured is very important in prognosis and treatment. Excellent recoveries occur in simple alveolar emphysema, especially those occurring acutely at pasture. This suggests that the lesion is functional and that the alveoli are not substantially damaged.

The pathophysiological consequences of emphysema depend upon the inefficiency of evacuation of pulmonary air-space and failure of normal gaseous exchange in the lungs. The elastic recoil of the tissue is diminished, and when the thorax subsides during expiration incomplete evacuation occurs. Because of the increase in residual volume, the tidal volume must be increased to maintain normal gaseous exchange. Retention of carbon dioxide stimulates an increase in the depth of respiration but maximum respiratory effort necessitated by exercise cannot be achieved. Anoxia develops and metabolism of all body tissues is reduced. The characteristic effect of emphysema is to produce an increase in expiratory effort necessitated by the failure of normal elastic recoil.

Interference with the pulmonary circulation results from collapse of much of the alveolar wall area and a consequent diminution of the capillary bed. The decreased negative pressure in the chest and the abnormally wide respiratory excursion also cause a general restriction
The combined effect of these factors may cause loud crackling lung sounds on auscultation. There is hypoxemia and, often, hypercapnia; mouth breathing is common.

CLINICAL FINDINGS
Characteristically, diffuse pulmonary emphysema causes severe expiratory dyspnea with a grunt on expiration and loud crackling lung sounds on auscultation over the emphysematous lungs. In severe cases in cattle, the emphysema is commonly interstitial and dissection of the mediastinum and fascial planes results in subcutaneous emphysema over the withers. In severe cases in cattle, open-mouth breathing is common.

In cattle and pigs the presence of pulmonary emphysema in pulmonary disease is often not detectable clinically.

CLINICAL PATHOLOGY
There is hypoxemia and, often, hypercapnia. Compensatory polycythemia may develop. There are no characteristic hematological findings but, if there is a significant secondary bronchopneumonia, a leukocytosis and left shift may be evident. In the appropriate location, an examination of feces for lungworm larvae may be desirable. In cases suspected of having an allergic origin, swabs of nasal secretion may reveal a high proportion of eosinophils and a hematological examination may show eosinophilia.

NECROPSY FINDINGS
The lungs are distended and pale in color and may bear imprints of the ribs. In interstitial emphysema the interalveolar septae are distended with air, which may spread to beneath the pleura, to the mediastinum and under the parietal pleura. There may be evidence of congestive heart failure. On histopathological examination a bronchiolitis is present in most cases. This may be diffuse and apparently primary or originate by spread from a nearby pneumonia.

TREATMENT
The treatment of pulmonary emphysema will depend on the species affected, the cause of the emphysema and the stage of the disease.

There is no known specific treatment for the pulmonary emphysema associated with acute interstitial pneumonia in cattle, which is discussed under that heading. The emphysema secondary to the infectious pneumonias will usually resolve spontaneously if the primary lesion of the lung is treated effectively. In valuable animals, the administration of oxygen may be warranted if the hypoxia is severe and life-threatening. Antihistamines, atropine and corticosteroids have been used for the treatment of pulmonary emphysema secondary to interstitial pneumonia in cattle but their efficacy has been difficult to evaluate.

PNEUMONIA
Pneumonia is inflammation of the pulmonary parenchyma usually accompanied by inflammation of the bronchioles and often by pleuritis. It is manifested clinically by an increase in the respiratory rate, changes in the depth and character of respirations, coughing, abnormal breath sounds on auscultation and, in most bacterial pneumonias, evidence of toxemia.

ETIOLOGY
Pneumonia may be associated with viruses, bacteria, or a combination of both, fungi, metazoan parasites and physical and chemical agents. Most of the pneumonias in animals are bronchogenic (inhalation) in origin but some originate by the hematogenous route, such as pneumonia of foals and calves with septicemia. The pneumonias which occur in farm animals are grouped here according to species.

Cattle
Pneumonic pasteurellosis (shipping fever) – *M. haemolytica*, *P. multocida* with or without parainfluenza-3 virus *Histophilus somnus* in feedlot cattle is not necessarily associated with the septicemic form of the disease. The role of the organism as a primary pathogen in acute bovine respiratory disease is uncertain.

- Pneumonia and arthritis in beef calves associated with *Mycoplasma bovis* and *Mycoplasma californicum*.
- Viral interstitial pneumonia in recently weaned beef calves associated with bovine respiratory syncytial virus; it may also occur in yearling and adult cattle.
- Contagious bovine pleuropneumonia – *Mycoplasma mycoides*.
- Acute and chronic interstitial pneumonia associated with *D. tyrtryptophane*, moldy hay and other pneumotoxic agents.
- Atypical interstitial pneumonia associated with *ryegrass staggers in calves*.
- Massive infestation with pig ascarid larvae.
- Lungworm pneumonia – *Dictyocaulus viviparous*.
- *Klebsiella pneumoniae* infection in calves and nursing cows with mastitis associated with this organism.
- Sporadically in tuberculosis associated with *M. bovis*.
- *Fusobacterium necrophorum* as a complication of calf diphtheria, and sporadically in feedlot cattle.
- There is a preliminary report of circovirus in adult cattle with pneumonia.
- Mycotic pneumonia associated with *Mortierella wolfii* in adult cattle.

- \textit{Pneumocystis} spp. in foals\textsuperscript{21}
- Mycotic pneumonia associated with \textit{Emmonsia crescens} (adiaspiromycosis) in adult horses\textsuperscript{22}
- Strenuous exercise in very cold conditions can cause damage to the airways of horses (and probably other species).\textsuperscript{23}

\textbf{Sheep}

Pneumonic pasteurellosis (\textit{Mannheimia} spp.) as acute primary pneumonia in feedlot lambs, or secondary to parainfluenza-3 or \textit{Chlamydia} sp. infection
- Newborn lambs – uncommonly \textit{Streptococcus zooepidemicus}, \textit{Salmonella abortus-ovis}
- Severe pneumonia due to \textit{Mycoplasma} sp. in lambs - kageda in Iceland and Switzerland
- Symptomless pneumonias without secondary infection – adenovirus, respiratory syncytial virus, reovirus, \textit{Mycoplasma} spp. (including \textit{M. ovis}-\textit{bovigenitalium}, \textit{M. dispar})\textsuperscript{24}
- \textit{Corynebacterium pseudotuberculosis} – sporadic cases only
- Melioidosis (\textit{Pseudomonas pseudomallei})
- Lungworm (\textit{Dictyocaulus filaria})
- Oxine herpesvirus-2\textsuperscript{25}
- Progressive interstitial pneumonia (maedi) and pulmonary adenomatosis (jaagsiene)
- Carbolic dip toxicity.

\textbf{Goats}

- Pleuropneumonia associated with \textit{Mycoplasma} strain F 38 or \textit{Mycoplasma capri}, a devastating disease
- Chronic interstitial pneumonia with \textit{cor pulmonale} as a common sequel may be associated with a number of \textit{Mycoplasma} spp., but \textit{M. mycoides} var. \textit{mycoides} appears to be the most commonly recorded
- Parainfluenza type 3\textsuperscript{26}
- Contagious ecthyma virus\textsuperscript{27}
- Retrovirus infection.

\textbf{All species}

- Toxoplasmosis – rare, sporadic cases
- Systemic mycoses
- Aspiration pneumonia is dealt with as a separate entity
- Sporadic secondary pneumonia associated with \textit{Streptococcus} sp., \textit{Corynebacterium} sp., \textit{Dermatophilus} sp.
- Interstitial pneumonia, pulmonary consolidation and fibrosis by toxins in plants – \textit{Eupatorium glandulosum} in horses, \textit{Zieria arborescens} (stinkwood) in cattle, \textit{Astragalus} spp. in all species.

\textbf{EPIDEMIOLOGY}

In addition to the infectious agents which cause the pneumonia, there are risk factors which contribute to the susceptibility of the animal. Three risk factors interact in the pathogenesis of specific pneumonias:

\textbf{Animal Environmental and management Pathogen.}

These are of paramount importance in any consideration of pneumonia and the details of the epidemiology of each specific pneumonia are presented with each specific disease in this book. As examples, some of the commonly recognized risk factors include:

- The weaning of beef calves in northern climates
- The long transportation of beef cattle to feedlots
- The collection and mixing of animals at auction marts where they might be deprived of feed and water for prolonged periods
- The transportation of Thoroughbred horses farther than 500 miles and viral respiratory tract disease or exposure to horses with respiratory tract disease\textsuperscript{28,29}
- Housing dairy calves in poorly ventilated overcrowded barns
- Marked changes in weather.

Susceptibility to pneumonia is determined by the animal’s resistance to infection by agents that cause or predispose to pneumonia. Factors that impair innate resistance or adaptive resistance (immunity) increase the animal’s susceptibility to pneumonia. For instance, shipping not only increases the risk of exposure of animals to pathogens to which they have not been exposed but also can impair innate resistance through damage to the respiratory tract by airborne irritants, dehydration, food deprivation and the effects of stress. There is a distinct trend evident since 1994 of increasing mortality from respiratory disease among cattle in feedlots,\textsuperscript{29} although the reasons have not been identified.

\textbf{PATHOGENESIS}

\textbf{Pulmonary defense mechanisms}

Under normal conditions the major airways and the lung parenchyma prevent the entry of and neutralize or remove injurious agents, so that the lung contains very few, if any, organisms beyond the large airways. Many infections of the respiratory tract originate from aerosolized particles carrying infectious agents that arise external to or within the respiratory tract. In order to induce an infection by the aerosol route, an etiological agent must be aerosolized, survive in the aerosol, be deposited at a vulnerable site in the respiratory tract of a susceptible host, and then multiply. Thus the pathogenesis of these respiratory infections is related to the deposition of particles and infectious agents within the respiratory tract.

Under normal conditions a complex of biochemical, physiological and immunological defense mechanisms protects the respiratory tract from inhaled particles that could be injurious or infectious. The major defense mechanisms of the respiratory tract include:

- Aerodynamic filtration by the nasal cavities
- Sneezing
- Local nasal antibody
- The laryngeal reflex
- The cough reflex
- Mucociliary transport mechanisms
- Alveolar macrophages
- Systemic and local antibody systems.
Most of the research on defense mechanisms has been done in man and in laboratory animals.

Respiratory mucociliary clearance

The mucociliary escalator has important functions in the lung's physical defenses against the constant challenge of inhaled pathogens. By various physical mechanisms, mucus traps and subsequently transports inhaled particles to the pharynx, where they are normally swallowed. Mucus also protects the airways by absorbing inhaled chemicals and gases, by humidifying the inspired air and by keeping the underlying mucosa hydrated. Mucus contains antibodies, especially IgA, which together with lactoferrin and lysozyme provide immunological defense.

Airway secretions consist of two layers. An underlying liquid layer, known as the periciliary fluid, in which the cilia beat, originates largely from trans¬epithelial osmosis. An overlying gel or mucus layer is composed of intertwined mucin strands. Airway mucus is secreted in small globules, which expand several hundredfold within seconds and are later drawn into stra¬nds and transported rostrally by ciliary activity.

The secretion of respiratory mucus is a protective mechanism by which inhaled particles touching the airway mucosa stimulate local mucus production, which then traps and transports the particles from the lung. Airway mucus is produced mainly by submucosal glands and goblet cells, also known as mucus-producing cells. Airway secretions also contain alveolar fluid, surfactant and alveolar cells, including macrophages, which are drawn into the mucociliary ladder by surface tension.

Airway mucus is a complex substance consisting of 95% water and a 5% combination of glycoproteins, proteoglycans, lipids, carbohydrates and minerals. Mucin is the main nonaqueous component. Effective mucociliary clearance or mucokinesis can occur over a range of mucus viscosity but very-low-viscosity mucus is poorly transported and tends to gravitate toward the alveoli, while excessively viscous mucus, which is also poorly transported, may lodge in the airways and become inspissated.

In respiratory disease mucociliary clearance is impaired through disruption of effective ciliary activity, or changes in the quantity or quality of the mucus or periciliary fluid, or all three factors. In viral pulmonary disease, ciliary activity can be disrupted because of temporary deciliation or lesions of the respiratory mucosa. The defective mucociliary clearance may also last for several weeks. In chronic obstructive pulmonary disease in the horse, metaplasia of ciliated epithelium to a nonciliated epithelium may occur in the smaller airways.

Changes in the quality of mucus are common in respiratory tract disease, especially increases in viscosity with pulmonary disease. The destruction of leukocytes and respiratory epithelial cells and the release of DNA increases the viscosity. Large increases in the glyco¬protein content of mucus also occur, which affects the mucokinetic properties. Purulent respiratory secretions have reduced elasticity and together with the increased viscosity affect the mucociliary clearance. Acute inflammation also results in the production of serum proteins from the airway exudate, which alters the viscoelasticity of mucus and further reduces mucokinesis.

Yellow or green respiratory secretions are due to the enzyme myeloperoxidase, released from leukocytes in the static secretion, or to high numbers of eosinophils.

The quantity of mucus increases in most cases of respiratory disease as a result of stimulation of goblet cells and submucosal glands by inflammatory mediators. The abnormal production can also exacerbate the original pulmonary dysfunction. Tracheal mucociliary clearance can be assessed endoscopically, in vivo, by dropping dye or small markers on the tracheal mucosa and measuring their rate of transit visually or using radioactive particles detected by scintigraphy.

Large particles in upper respiratory tract

Large aerosolized particles that are inhaled are removed by the nasal cavities and only small ones are able to get into the lung. In the upper respiratory tract, essentially 100% of particles more than 10 μm in diameter and 80% of particles of the 5 μm size are removed by gravitational settling on mucosal surfaces. Particles deposited between the posterior two-thirds of the nasal cavity and the nasopharynx and from the larynx to the terminal bronchioles land on airways lined by mucus-covered, ciliated epithelium and are removed by means of the mucociliary transport mechanism. The nasopharyngeal and tracheobronchial portions of the ciliated airways transport mucus toward the pharynx, where it can be eliminated by swallowing. The cilia beat most effectively in mucus at a certain elasticity, viscosity and chemical composition. Anything that interferes with the secretion and maintenance of normal mucus will interfere with the clearance of particles from the upper respiratory tract. The damaging effect of viruses on mucociliary clearance has been demonstrated in laboratory animals and in humans.

Mycoplasma pneumoniae infection slows tracheobronchial clearance for as long as 1 year, suggesting a possible explanation for the predisposition to bacterial pneumonia commonly observed after these infections. Viral diseases of the upper respiratory tract of farm animals are common and a similar interference in the mucociliary transport mechanism may explain the occurrence of secondary bacterial pneumonia.

Cough reflex

The cough reflex provides an important mechanism by which excess secretions and inflammatory exudates from the lungs and major airways can be removed from the airways and disposed of by expectoration or swallowing. In animals with relatively normal lungs, coughing represents a very effective means of expelling inhaled foreign bodies, or excessive or abnormal respiratory secretions, down to the level of the fourth- or fifth-generation bronchi. If the airways become deciliated, the cough reflex is the main and only mucus-clearance mechanism remaining. The cough reflex is valuable for transporting the increased secretions present in equine pulmonary disease and antitussive agents should therefore not be used in horses.

In the presence of severe tracheitis and pneumonia, coughing may result in retrograde movement of infected material to the terminal respiratory bronchioles and actually promote spread of the infection to distal parts of the lung. Any process that causes airway obstruction can predispose the lung to secondary bacterial infections. Experimental obstruction of the bronchi supplying a lobe of lung in sheep allows the development of secondary bacterial pneumonia. It has been postulated that damage to small airways following viral infections may allow the accumulation of exudate and cellular debris, which may facilitate secondary bacterial infections.

Small particles into lower respiratory tract

Particles of 1–2 μm size settle in the lungs through the action of gravity in the alveolar spaces and particles below 0–2 μm settle through diffusion of air. The alveolar macrophage plays a major role in clearing inhaled particles from the lung. Under normal conditions, bacteria that gain entry into the alveoli are cleared quickly and effectively in a matter of hours. Experimental parainfluenza-3 (PI-3) virus infection has the greatest adverse effect on the pulmonary clearance of M. haemolytica administered by intranasal aerosol on the seventh day following viral infection. The effect on pulmonary clearance is much less when the bacteria are given on the third or 11th day following the initial viral infection.
The presence of pre-existing antibody to *M. haemolytica* eliminates the effect of the viral infection on pulmonary clearance. Thus there is some evidence that in domestic animals lung clearance mechanism may be affected by a concurrent viral infection. This may have major implications in the control of some of the common infectious respiratory diseases of farm animals.

**Species susceptibility**

The anatomical and physiological features of the respiratory system of cattle may predispose them to the development of pulmonary lesions much more than other farm animal species. Cattle have a small physiological gaseous exchange capacity and greater resultant basal ventilatory activity. The small gaseous exchange capacity may predispose cattle to low bronchiolar or alveolar oxygen levels during exposure to high altitudes and during periods of active physical or metabolic activity. During these times, low oxygen tension or hypoxia may slow mucociliary and alveolar macrophage activity and decrease pulmonary clearance rates. The basal ventilatory activity is comparatively greater than other mammals, which results in the inspired air becoming progressively more contaminated with infectious, allergenic or noxious substances.

The bovine lung also has a higher degree of compartmentalization than other species. This may predispose to airway hypoxia peripheral to Airways that become occluded. This results in reduced phagocytic activity and the retention or multiplication of infectious agents. In addition, because of the low numbers of alveolar macrophages in the bovine lung the pulmonary clearance mechanism may not be as effective as in other species. There is also a low level atypical bioactivity of lysozyme in bovine respiratory mucus, which may make cattle more susceptible to infection of the respiratory tract than other species.

**Development of pneumonia**

The process by which pneumonia develops varies with the causative agent and its virulence and with the portal by which it is introduced into the lung.

**Bacteria are introduced** largely by way of the respiratory passages and cause a primary bronchiolitis that spreads to involve surrounding pulmonary parenchyma. The reaction of the lung tissue may be in the form of an acute fibrinous process as in pastureellosis and contagious bovine pleuropneumonia, a necrotizing lesion as in infection with *F. necrophorum* or as a more chronic caseous or granulomatous lesion in mycobacterial or myotic infections. Spread of the lesion through the lung occurs by extension but also by passage of infective material along bronchioles and lymphatics. Spread along the air passages is facilitated by the normal movements of the bronchiolar epithelium and by coughing. Bronchiectasis and pulmonary abscesses are complications and common causes of failure to respond to therapy. Hematogenous infection by bacteria results in a varying number of septic foci, which may enlarge to form lung abscesses. Pneumonia occurs when these abscesses rupture into air passages and spread as a secondary bronchopneumonia.

**Viral infections** are also introduced chiefly by inhalation and cause a primary bronchiolitis, but there is an absence of the acute inflammatory reaction that occurs in bacterial pneumonia. Spread to the alveoli causes enlargement and proliferation of the alveolar epithelial cells and the development of alveolar edema. Consolidation of the affected tissue results but again there is an absence of acute inflammation and tissue necrosis so that toxemia is not a characteristic development. Histologically the reaction is manifested by enlargement and proliferation of the alveolar epithelium, alveolar edema, thickening of the interstitial tissue and lymphocytic aggregations around the alveoli, blood vessels and bronchioles. This interstitial type of reaction is characteristic of viral pneumonias.

The **pathophysiology** of all pneumonias, regardless of the way in which lesions develop, is based upon interference with gaseous exchange between the alveolar air and the blood. Anoxia and hypercapnia develop, which results in polypnea, dyspnea or tachypnea. Consolidation results in louder than normal breath sounds, especially over the anteroventral aspects of the lungs, unless a pleural effusion is present to muffle the sounds. In bacterial pneumonias there is the added effect of toxins produced by the bacteria and necrotic tissue; the accumulation of inflammatory exudate in the bronchi is manifested by abnormal lung sounds such as crackles and wheezes on auscultation. Interstitial pneumonia results in consolidation of pulmonary parenchyma without involvement of the bronchi, and on auscultation loud breath sounds predominate in the early stages.

**Extension of the pneumonia** to the visceral surface of the pleura results in pleuritis, pleuropneumonia, pleural effusion and thoracic pain. Fibrinous pleuritis is a common complication of pneumonic pasteurellosis in cattle. Pleuritis and pleural effusion secondary to pneumonia and pulmonary abscesses are commonly recognized in adult horses with the pleuropneumonia complex associated with aerobic and anaerobic bacteria. Anaerobic bacterial pleuropneumonia in the horse is accompanied by a putrid odor of the breath, the sputum or the pleural fluid. It is suggested that most anaerobic bacterial pulmonary infections in the horse are the result of aspiration of oropharyngeal contents, and are most commonly located in the right lung because of the proximity of the right main stem bronchus. Some horses with pleuropneumonia may develop acute hemorrhagic pulmonary infection and necrotizing pneumonia.

Restriction of gaseous exchange occurs because of the obliteration of alveolar spaces and obstruction of air passages. In the stage before blood flow through the affected part ceases, the reduction in oxygenation of the blood is made more severe by failure of part of the circulating blood to come into contact with oxygen. Cyanosis is most likely to develop at this stage and to be less pronounced when heparinization is complete and blood flow through the part ceases. An additional factor in the production of anoxia is the shallow breathing that occurs. Pleuritic pain causes reduction in the respiratory excursion of the chest wall but when no pleurisy is present the explanation of the shallow breathing probably lies in the increased sensitivity of the Hering–Breuer reflex. Retention of carbon dioxide with resulting acidosis is most likely to occur in the early stages of pneumonia because of this shallow breathing.

**Clinical findings**

- **Rapid, shallow breathing** is the cardinal sign of early pneumonia
- **Dyspnea** occurs in the later stages when much of the lung tissue is nonfunctional
- **Polypnea** may be quite marked with only minor pneumonic lesions; the rapidity of the respiration is an inaccurate guide to the degree of pulmonary involvement
- **Coughing** is another important sign, the type of cough varying with the nature of the lesion.

Bacterial bronchopneumonia is usually accompanied by a moist and painful cough. In viral interstitial pneumonia the coughing is frequent, dry and hacking, often in paroxysms. Auscultation of the thorax before and after coughing may reveal coarse crackling sounds suggestive of exudate in the airways. Cyanosis is not a common sign and occurs only when large areas of the lung are affected. A nasal discharge may or may not be present, depending upon the amount of exudate present in the bronchioles and whether or not there is accompanying inflammation of the upper respiratory tract. The odor of the breath may be informative: it may have an odor of decay.
when there is a large accumulation of inspissated pus present in the air passages; or it may be putrid, especially in horses affected with anaerobic bacterial pleuropneumonia.

In acute bacterial bronchopneumonia, toxemia, anorexia, depression, tachycardia and a reluctance to lie down are common. In the advanced stages, severe dyspnea with an expiratory grunt are common. Lush pasture within the previous ammonia of cattle, severe respiratory failure.

In viral interstitial pneumonia, affected animals are usually not toxemic but they may have a fever and be inaptept or anorexic. However, some cases of viral interstitial pneumonia can be diffuse and severe and cause severe respiratory distress, failure to respond to therapy and death within a few days. A severe bronchointerstitial pneumonia of foals aged 1–2 months of age has been described.14,32 The disease was characterized clinically by sudden onset of fever and increasingly severe dyspnea with respiratory distress and no response to treatment. In acute interstitial pneumonia of cattle, exemplified by the acute disease seen in mature cattle moved on to a lush pasture within the previous 10 days, some animals may be found dead. Other affected animals are severely dyspneic, arrouxious, commonly mouth-breathing and grunting with each expiration and, if forced to walk, may collapse and die of asphyctic respiratory failure.

Auscultation of the lungs is a valuable aid to diagnosis. The stage of development and the nature of the lesion can be determined and the area of lung tissue affected can be outlined. In the early congestive stages of broncho-pneumonia and interstitial pneumonia the breath sounds are increased, especially over the anterolateral aspects of the lungs. Crackles develop in broncho-pneumonia as bronchiolar exudation increases, but in uncomplicated interstitial pneumonia, clear, harsh breath sounds are audible. In viral interstitial pneumonia, wheezes may be audible due to the presence of bronchiolitis. When complete consolidation occurs in either form, loud breath sounds are the most obvious sound audible over the affected lung but crackles may be heard at the periphery of the affected area in broncho-pneumonia. Consolidation also causes increased audibility of the heart sounds. When pleurisy is also present a pleuritic friction rub may be audible in the early stages, and muffling of the breath sounds over the ventral aspects of the lungs in the late exudative stages. If a pleural effusion is present, percussion of the thorax will reveal dullness of the ventral aspects and a fluid line can usually be outlined. Consolidation can be detected also by percussion of the thorax.

In chronic bronchopneumonia in cattle there is chronic toxemia, rough hair coat and a gaunt appearance. The respiratory and heart rates are above normal and there is usually a moderate persistent fever. However, the temperature may have returned to within a normal range even though the animal continues to have chronic incurable pneumonia. The depth of breathing is increased and both inspiration and expiration are prolonged. A grunt on inspiration and open-mouth breathing indicate advanced pulmonary disease. A copious bilateral mucopulent nasal discharge and a chronic moist productive cough are common. On auscultation of the lungs, loud breath sounds are usually audible over the ventral half of the lungs, and crackles and wheezes are commonly audible over the entire lung fields but are most pronounced over the ventral half.

With adequate treatment in the early stages, bacterial pneumonia usually responds favorably in 24 hours but viral pneumonia may not respond at all or may relapse after an apparent initial beneficial response. The transient response may be due to control of the secondary bacterial invaders. In some bacterial pneumonias, it may also occur that are due either to reinfection or to persistence of the infection in necrotic foci that are inaccessible to antimicrobials. The final outcome depends on the susceptibility of the causative agent to the treatments available and the severity of the lesions when treatment is undertaken. Pleurisy is a common complication of pneumonia and rarely occurs independently of it, and is described later under that heading.

Pneumonia and pleuritis in horses are described separately (see Equine pleuropneumonia, below). Congestive heart failure or cor pulmonale may occur in some animals which survive a chronic pneumonia for several weeks or months.

Medical imaging
Thoracic radiography and ultrasonography are now commonly performed in veterinary teaching hospitals and specialty clinics. They can provide considerable diagnostic assistance in assessing the severity of the lesion and explaining certain clinical manifestations that may be difficult to interpret. Ultrasonography is a useful diagnostic aid in cattle and horses with anaerobic bacterial pleuropneumonia and pulmonary abscessation.33,34 Gas echoes within pleural or abscess fluid were found to be a sensitive and specific indicator of anaerobic infection as was a putrid breath or pleural fluid.

In cattle with pleuropneumonia, ultrasonographic examination of both sides of the thorax may reveal accumulations of anehogenic and hypoeogenic fluid in the pleural space in the ventral aspect of the thorax.35-35 In cattle, pleural effusion associated with pleuritis is usually unilateral because the pleural sacs do not communicate. Bilateral pleural effusion may indicate either bilateral pulmonary disease or a noninflammatory cause such as right-sided congestive heart failure or hypoproteinemia.

CLINICAL PATHOLOGY
Respiratory secretions
The laboratory examination of the exudates and secretions of the respiratory tract is the most common diagnostic procedure performed when presented with cases of pneumonia. Nasal swabs, tracheobronchial aspirates and bronchoalveolar lavage samples can be submitted for isolation of viruses, bacteria and fungi, cytological examination and determination of antimicrobial sensitivity. Tracheobronchial aspirates are considered more reliable for the cytological examination of pulmonary secretions in horses with suspected pneumonia or pleuropneumonia. Bronchoalveolar lavage samples may be normal in horses affected with pneumonia or pleuropneumonia. In suspected cases of pleuropneumonia the collection and culture of pleural fluid is a valuable aid to diagnosis10 and both anaerobic and aerobic bacteria must be considered.

Thoracocentesis
When pleural effusion is suspected, thoracocentesis can be used to obtain pleural fluid for analysis.

Hematology
Hematological examination can indicate if the infection is bacterial or viral in nature and its severity. The hematocrit will be elevated in severely toxemic animals that are not drinking water. Severe bacterial bronchopneumonia and pleuritis is characterized by marked changes in the leukon. Serum fibrinogen concentrations are markedly elevated in horses with pleuropneumonia and pleuritis.37 Some limited studies indicate that the measurement of acute-phase proteins in bovine respiratory disease may be a valuable diagnostic and prognostic aid.38

Serology
When viral interstitial pneumonia is suspected, acute and convalescent sera are recommended for viral neutralization titer evaluation. For specific diseases such as porcine pleuropneumonia, serum can be taken from a percentage of the herd and submitted for serotyping to determine which serotype is most prevalent in the herd.
Fecal samples
When lungworm pneumonia is suspected, fecal samples can be submitted for detection of the larvae.

Necropsy
In outbreaks of respiratory disease where, in the diagnosis is uncertain, necropsy of selected early cases will often assist in making a diagnosis.

Necropsy findings
Gross lesions are usually observed in the anterior and dependent parts of the lobes; even in fatal cases where much of the lung is destroyed, the dorsal parts of the lobes may be unaffected. The gross lesions vary a great deal depending upon the type of pneumonia present. Bronchopneumonia is characterized by the presence of serofibrinous or purulent exudate in the bronchioles, and lobular congestion or hepatization.

In the more severe, fibrinous forms of pneumonia there is gelatinous exudation in the interlobular septae and an acute pleurisy, with shreds of fibrin present between the lobes.

In interstitial pneumonia the bronchioles are clean and the affected lung is sunken, dark red in color and has a granular appearance under the pleura and on the cut surface. There is often an apparent firm thickening of the interlobular septae. These differences are readily detected on histological examination.

In chronic bronchopneumonia of cattle there is consolidation, fibrosis, fibrinous pleuritis, interstitial and bullous emphysema, bronchi filled with exudate, bronchiectasis and pulmonary abscessation.

Lesions typical of the specific infections listed under etiology are described under the headings of the specific diseases.

TREATMENT
Antimicrobial therapy
In specific bacterial infections as listed above, isolation of affected animals and careful surveillance of the remainder of the group to detect cases in the early stages should accompany the administration of specific antimicrobials to affected animals. The choice of antimicrobial will depend on the tentative diagnosis, the experience with the drug in previous cases and the results of drug sensitivity tests. The common bacterial pneumonias of all species will usually recover quickly (24–72 h) if treated with an adequate dose of the drug of choice early in the course of the disease. Animals with severe pneumonia will require daily treatment for several days until recovery occurs. Those with bacterial pneumonia and toxemia must be treated early on an individual basis. Each case should be identified and carefully monitored for failure to recover, and an assessment made. Clinical field trials to evaluate different antimicrobials for the treatment of acute bovine respiratory disease occurring under natural conditions are becoming more common and more meaningful, particularly under commercial feedlot conditions.

Antimicrobial agents in a long-acting base may be used to provide therapy over a 4–6-day period instead of the daily administration of the shorter-acting preparations. However, the blood levels from the long-acting preparations are not as high as the shorter-acting preparations and treatment with these compounds are not as effective in severely affected animals.

Selection of antimicrobials is based on the principles detailed in Chapter 4. Briefly, antimicrobials for treatment of bacterial respiratory disease should be active against the causative agent, should be able to achieve therapeutic concentrations in diseased lung and should be convenient to administer. The antimicrobials should be affordable and, if used in animals intended as human food, must be approved for use in such animals.

Antimicrobials for treatment of lung disease are preferably those that achieve therapeutic concentrations in diseased lung tissue after administration of conventional doses. This has been convincingly demonstrated for the macrolide (azithromycin, erythromycin), triamidine

Differential diagnosis

There are two major difficulties in the clinical diagnosis of pneumonia. The first is to decide that the animal has pneumonia; the second is to determine the nature of the pneumonia and its cause. The suspected cause will influence the prognosis, the clinical management and, more particularly in infectious pneumonias, the kind of antimicrobial therapy used.

There are two kinds of errors made in the clinical diagnosis of pneumonia. One is that the pneumonia is not detected clinically because the abnormal lung sounds are apparently not obvious. The other is to make a diagnosis of pneumonia because of the presence of dyspnea that is due to disease in some other body system.

- In bacterial pneumonia the major clinical findings are polyneumia in the early stages and dyspnea later, abnormal lung sounds, and fever and toxemia.
- In viral interstitial pneumonia uncomplicated by secondary bacterial pneumonia, there is no toxemia. Pulmonary edema and congestion, embolism of the pulmonary artery and emphysema are often mistaken for pneumonia but can usually be differentiated by the absence of fever and toxemia, on the basis of the history and on auscultation findings.
- Diseases of other body systems may cause polyneumia and dyspnea. Congestive heart failure, the terminal stages of anemia, poisoning by histotoxic agents such as hydrocyanic acid, hyperthermia and acidosis are accompanied by respiratory embarrassment but not by the abnormal sounds typical of pulmonary involvement.

If pneumonia is present the next step is to determine the nature and cause of the pneumonia. All the practical laboratory aids described earlier should be used when necessary. This is of particular importance when outbreaks of pneumonia are encountered, in which case necropsy examination of selected cases is indicated. In single routine cases of pneumonia the cause is usually not determined. However, the age and class of the animal, the history and epidemiological findings and the clinical findings can usually be correlated and a presumptive etiological diagnosis made.

- Pleuritis is characterized by shallow, abdominal-type respiration, by pleuritic friction sounds when effusion is minimal, a muffling of lung sounds on auscultation, the presence of dullness and a horizontal fluid line on acoustic percussion when there is sufficient pleural fluid present. Thoracocentesis reveals the presence of fluid.
- In pneumothorax there is inspiratory dyspnea and on the affected side the abnormalities include:
  - Absence of breath sounds over the lobes but still audible sounds over the base of the lung.
  - Increase in the absolute intensity of the heart sounds.
  - Increased resonance on percussion.

Diseases of the upper respiratory tract such as laryngitis and tracheitis are accompanied by varying degrees of inspiratory dyspnea, which is often loud enough to be audible without a stethoscope. In less severe cases, auscultation of the mid-cervical trachea will reveal moist wheezing sounds on inspiration. These sounds are transmitted down into the lungs and are audible on auscultation of the thorax. These transmitted sounds must not be interpreted as due to pneumonia. In some cases of severe laryngitis and tracheitis the inspiratory sounds audible over the trachea and lungs are markedly reduced because of almost total obliteration of these organs. In laryngitis and tracheitis there is usually a more frequent cough than in pneumonia and the cough can be readily stimulated by squeezing the larynx or trachea. In pneumonia the abnormal lung sounds are audible on both inspiration and expiration. Examination of the larynx through the oral cavity in cattle and with the aid of a rhinolaryngoscope in the horse will usually reveal the lesions.
There is no specific treatment for the viral pneumonias and while many of the *Mycoplasma* spp. are sensitive to antimicrobials in vitro, the pneumonias associated with them do not respond favorably to treatment. This may be due to the intracellular location of the *Mycoplasma* making them inaccessible to the drugs. Because viral and mycoplasmal pneumonias are commonly complicated by secondary bacterial infections, it is common practice to treat acute viral and mycoplasmal pneumonias with antimicrobials until recovery is apparent.

### Intensive and prolonged therapy

May be required for the treatment of diseases such as equine pleuropneumonia. It may include daily care and treatment in a veterinary clinic consisting of daily lavage of the pleural cavity including thoracostomy to drain pulmonary abscesses, and intensive antimicrobial therapy and monitoring for several weeks.

### Mass medication

In outbreaks of pneumonia where many animals are affected and new cases occur each day for several days, the use of mass medication of the feed and/or water supplies should be considered. Outbreaks of pneumonia in swine herds, lamb feedlots, veal calf enterprises and beef feedlots, are usually ideal situations for mass medication through the feed or water. Mass medication may assist in the early treatment of subclinical pneumonia and is a labor-saving method of providing convalescent therapy to animals that have been treated individually. The major limitation of mass medication is the uncertainty that those animals that need the drug will actually get it in the amounts necessary to be effective. Total daily water intake by animals is a function of total dry matter intake and wellbeing, and the water consumption is therefore markedly reduced in toxemic animals. The provision of a reliable concentration of the drug in the water supply on a 24-hour basis is also a problem. However, with careful calculation and monitoring, mass medication can be a valuable and economical method of treating large numbers of animals. The method of calculating the amount of antimicrobials to be added to feed or water supplies is presented in Chapter 4 on antimicrobial therapy.

When outbreaks of pneumonia occur and new cases are being recognized at the rate of 5–10% per day of the total in the group, all the remaining in-contact animals may be injected with an antimicrobial in a long-acting base. This may help to treat subclinical cases before they become clinical and thus control the outbreak.

### Other drugs

Nonsteroidal anti-inflammatory drugs are useful in the treatment of infectious respiratory disease of cattle and horses, and likely other species. The drugs act by inhibiting the inflammatory response induced by the infecting organism and tissue necrosis. Meloxicam (0.5 mg/kg subcutaneously, once), when administered with tetracycline, improves weight gain and reduces the size of lesions in lungs of cattle with bovine respiratory disease complex over those of animals treated with tetracycline alone. NSAIDs also improve the clinical signs of cattle with respiratory disease. Use of these drugs is routine in horses with pneumonia or pleuritis.

Corticosteroids have been used for their anti-inflammatory effect in the treatment of acute pneumonia. However, there is no clinical evidence that they are beneficial.

Bronchodilators have been investigated in the treatment of pneumonia in food animals. The beta-2 adrenergic agonists are potent and effective bronchodilators that can be administered orally, intravenously or by inhalation. These drugs also enhance mucociliary clearance of material from the lungs. Most administration is orally or by inhalation. The use of beta-2 adrenergic agonist bronchodilator drugs in food animals is not permitted in most countries because of the risk of contamination of foodstuffs intended for consumption by people. This is particularly the case with clenbuterol, a drug approved in many countries for use in horses that is administered to cattle illicitly as a growth promoter. People can be poisoned by clenbuterol in tissues of treated cattle. Theophylline has been evaluated as a bronchodilator to relieve respiratory distress in cattle with pneumonia. When it was given orally at a dose of 28 mg/kg BW daily for 3 days, along with antimicrobial therapy, to calves with naturally acquired respiratory disease, the respiratory rate and rectal temperature decreased. However, some calves died, presumably from the accumulation of lethal concentrations of plasma theophylline. It is recommended that the drug should not be used unless plasma levels can be monitored.

### Supportive therapy and housing

Affected animals should be housed in warm, well-ventilated, draft-free accommodation and provided with ample fresh water and light, nourishing food. During convalescence premature return to work or exposure to inclement weather should be avoided. If the animal does not eat, oral or parenteral force-feeding should be instituted. If fluids are given intravenously
care should be exercised over the speed with which they are administered. Injection at too rapid a rate may cause overloading of the right ventricle and death due to acute heart failure.

Supportive treatment may include the provision of oxygen, if it is available, especially in the critical stages when hypoxia is severe. In foals the oxygen can be provisioned for several hours. Oxygen therapy is detailed in the general section on treatment of respiratory disease above.

ASPIRATION PNEUMONIA

Aspiration or inhalation pneumonia is a common and serious disease of farm animals. Cases occur after careless drenching or passage of a stomach tube during treatment for other illness, for example administration of mineral oil to horses with colic. Even when care is taken these procedures are not without risk. Other causes include the feeding of calves and pigs on fluid feeds in inadequate troughing, inhalation occurring in the struggle for food. Dipping of sheep and cattle when they are weak, or keeping their heads under for too long, also results in inhalation of fluid. Vomiting in ruminants and horses may be followed by aspiration, especially in cattle with parturient paresis or during the passage of a stomach tube if the head is held high. Rupture of a pharyngeal abscess during palpation of the pharynx or passage of a nasal tube may cause sudden aspiration of infective material. Animals suffering from paralysis or obstruction of the larynx, pharynx, or esophagus may aspirate food or water when attempting to swallow. Aspiration pneumonia is the consistent lesion of crude oil poisoning in cattle and probably results from vomiting or regurgitation.2

Lipid pneumonia

Lipid pneumonia usually results from aspiration of mineral oil (liquid paraffin) administered for gastrointestinal disease. Pneumonia is sometimes the result of inadvertent administration of the oil into the trachea through a misplaced stomach tube, or inhalation following oral administration of oil. However, aspiration of oil can occur even when it is delivered into the stomach through a nasogastric tube, presumably because of regurgitation of oil either around the tube or after the tube has been removed. Administration of oil to sedated or severely depressed animals may increase the risk of aspiration.

Clinical signs include cough, tachypnea, tachycardia, pyrexia, respiratory distress and abnormal lung sounds. Radiographs can reveal an alveolar and interstitial pattern. Examination of tracheal aspirates reveals a neutrophilic inflammation and the presence of lipid. Lipid can be readily identified by Sudan or oil red O staining of smears of the aspirate in acute cases. Necropsy examination reveals consolidated lungs. On cut section of these areas oil can be visible. Chronic cases have tissue necrosis and severe interstitial pneumonia. Lipid droplets can be identified in affected lung tissue after oil red O staining of sections.4 The presence and nature of the lipid can be demonstrated by thin-layer chromatography and gas chromatography.4 The prognosis for recovery is poor. Treatment is supportive and includes anti-inflammatory drugs, antimicrobials, and oxygen. There is no specific treatment. Prevention includes careful insertion of nasogastric tubes, verification of their placement in the stomach and not administering mineral oil to animals with a distended stomach or ones that are heavily sedated or severely depressed.

Esophageal obstruction

Esophageal obstruction is a common and important cause of pneumonia in horses.2,5 Of 18 horses with esophageal obstruction that had thoracic radiographs performed, eight had evidence of aspiration pneumonia.2 Obstruction of the esophagus in horses, and in other species, leads to the accumulation of saliva and feed material in the esophagus oral to the obstruction. When the esophagus is full, this material accumulates in the pharynx with subsequent aspiration into the trachea resulting in contamination of the trachea and lower airways with feed material and oropharyngeal bacteria. Feed material is irritant and also causes obstruction of the smaller airways. Pulmonary defense mechanisms are weakened or overwhelmed by the contamination and infection and pneumonia result. The duration of esophageal obstruction is a good indicator of the risk of aspiration pneumonia, although the extent of contamination of the trachea with feed material is not.3 Affected horses are pyrexic, tachycardic, and toxemic. Lung sounds can include crackles and wheezes, but the only auscultatory abnormality can be decreased breath sounds in the ventral thorax. Radiography reveals a characteristic pattern of bronchopneumonia restricted, at least initially, to the cranioventral and caudodorsal lung lobes in adult horses. Ultrasonography reveals comet tail lesions in the ventral lung fields and variable consolidation. Pleuritis is a not uncommon sequel to aspiration pneumonia. Examination of tracheal aspirates demonstrates neutrophilic inflammation with presence of degenerate neutrophils, bacteria that are both intracellular and extracellular, and plant material. Culture of tracheal aspirates yields one or more of a wide variety of...
bacteria including *S. zooepidemicus*, *Pasteurella sp.*, *Actinobacillus sp.*, *E. coli*, and anaerobes. Treatment involves prompt relief of the esophageal obstruction and administration of broad-spectrum antimicrobials such as a combination of penicillin, aminoglycoside, and metronidazole. The prognosis for recovery from aspiration pneumonia secondary to esophageal obstruction is guarded to fair, partly because the animal has to recover from two diseases—the pneumonia and the esophageal obstruction. Prevention of aspiration pneumonia in horses with esophageal obstruction includes prompt relief of the obstruction and administration of broad-spectrum antimicrobials.

**Meconium aspiration syndrome**

Aspiration of meconium during parturition is associated with severe lung disease in newborns. Passage of meconium in utero, and subsequent aspiration by the fetus, is a sign of fetal distress. It is suggested that fetal distress results in expulsion of meconium into the amniotic fluid. This is followed by aspiration of contaminated amniotic fluid. The passage of meconium-contaminated amniotic fluid into the lungs may occur prior to birth when the fetus gasps for air in an attempt to correct hypoxemia or when the calf takes its first breath and aspirates meconium from the oropharynx. Normally, fetal aspiration of amniotic fluid does not occur because the inspiratory forces are insufficient to allow amniotic fluid to reach the lungs, and the lung liquid, a locally produced viscous material present in the trachea and lungs, constantly flows up the major airways to the oropharynx. The result is that the fetus is doubly challenged in that it must deal with both the cause of the fetal distress and the pneumonia induced by aspiration of meconium. Although meconium is sterile, it induces a severe inflammatory response in the lungs.

The *meconium aspiration syndrome* is best described in newborn calves, although there are numerous reports of its experimental induction in piglets and lambs as a model of the human disease. In a series of calves under 2 weeks of age submitted to a diagnostic laboratory, 42.5% had evidence of meconium, squamous cells or keratin in the lung. Diffuse alveolitis with edema of neutrophils, macrophages, multinucleated cells and obstruction of small airways with atelectasis were common.

Treatment of aspiration pneumonia in farm animals is not well described. Administration of antimicrobials is prudent. Anti-inflammatory drugs are indicated. Pentoxifylline is used in human neonates with meconium aspiration, but there are no reports of its use for this purpose in farm animals.

**Dusty feed**

Although farm animals fed on dusty feeds inhale many dust particles and bacteria, which can be readily isolated from the lung, this form of infection rarely results in the development of pneumonia. Much of the dust is filtered out in the bronchial tree and does not reach the alveoli. However, this may be of importance in the production of the primary bronchiolitis that so often precedes alveolar emphysema in horses. The inhalation of feed particles in pigs in a very poorly ventilated environment has been demonstrated to cause foreign body pneumonia. Also, a dry, dusty atmosphere can be created in a pig sty by overfrequent changing of wood shavings used as bedding, and this can lead to the production of foreign body pneumonia. Liquids and droplets penetrate to the depths of the alveoli and run freely into the dependent portions, and aspiration pneumonia often results.

**Caudal Vena Cava Thrombosis (Posterior Vena Cava Thrombosis) and Embolic Pneumonia in Cattle**

Embolic pneumonia as a sequel to thrombosis of the posterior vena cava is a relatively common disease of cattle in Europe and the UK. The disease is rare in cattle less than 1 year old although it can occur at any age. A preponderance of affected animals are in feedlots on heavy grain diets and there are peaks of incidence at those times of the year when most cattle are on such diets. There is an obvious relationship between the occurrence of this disease and that of hepatic abscessation arising from lactic-acid induced rumenitis on heavy grain diets.

**Emboli**

Emboli are formed in the liver and enter the vena cava posthepatically to lodge in the pulmonary artery. When these emboli lodge in the lobar arteries they produce multiple small hemorrhages. These emboli then travel on to the smaller pulmonary arteries where they may lodge in the lung, or may pass further into the pulmonary circulation, usually via the bronchial arteries, and lodge in the lower lobes.

**The etiology and pathogenesis**

of the disease are based on the development of a thrombus in the posterior vena cava and the subsequent shedding of emboli, which lodge in the pulmonary artery causing embolism, endarteritis, multiple pulmonary abscesses, and chronic suppurative pneumonia. Pulmonary hypertension develops in the pulmonary artery, leading to the development of aneurysms, which may rupture causing massive intrapulmonary or intrabronchial hemorrhage. In most cases the thrombi in the vena cava originate from hepatic abscesses, or postdiaphragmatic abscesses. Usually there is an initial phlebitis and the subsequent thrombus extends into the thoracic part of the vessel. When the thrombus occludes the openings of the hepatic veins into the vena cava, there is congestion of the liver and hepatomegaly, ascites, and abdominal distension in some of these cases.

**The most common form** of the disease is characterized by manifestations of respiratory tract disease. Commonly there is a history of the disease for a few weeks or longer but some animals are ‘found dead’ without prior recorded illness. There is usually fever and an increase in the rate and depth of respiration, coughing, epistaxis and hemoptysis, anemia with pallor, a hemic murmur, and a low packed cell volume. Respirations are painful and a mild expiratory grunt or groan may be audible with each respiration. Subcutaneous emphysema and frothing at the mouth are evident in some. Deep palpation in the intercostal spaces and over the xiphoid sternum may elicit a painful grunt. The lungs sounds may be normal in the early stages but, with the development of pulmonary arterial lesions, embolic pneumonia and collapse of affected lung, widespread rhonchi are audible on auscultation. There can be ascites.1 In one series of cases the presence of anemia, hemoptysis, epistaxis, and widespread abnormal lungs sounds were characteristic features of the disease.3 There are accompanying nonspecific signs of inappetence, ruminal stasis and scant feces.

About one-third of affected cattle become progressively worse over a period of 2–18 days with moderate to severe dyspnea, and die of acute or chronic anemia or are euthanized on humane grounds. Almost half of the cases die suddenly as a result of voluminous intrapulmonary hemorrhage. It is probably the only common cause in cattle of acute hemorrhage from the respiratory tract that causes the animal to literally drop dead. The remainder have a brief, acute illness of about 24 hours.

Some evidence of hepatic involvement is often present, including enlargement of the liver, ascites, and melena. Chronic cor pulmonale develops in some with attendant signs of congestive heart failure.

**Radiography** of the thorax of some affected animals has found an increase in lung density and markings. These are irregular, focal or diffuse, and nonspecific. More distinct opacities are present in some and are referable to embolic infarcts and larger pulmonary hemorrhages. Radiographic abnormalities in the lungs are detected in approximately one-third of cows with caudal vena cava thrombosis.2 **Ultrasoundography** can be a useful diagnostic aid in detecting changes in the caudal vena cava.2,3 The caudal vena cava in affected cows is round to oval rather
than the triangular shape in normal cattle,2 and the hepatic, splenic, and portal veins can be dilated.

There is typically anemia and leukocytosis. Neutrophilia with a regenerative left shift and hypergammaglobulinemia due to chronic infection are common. Serum gamma-glutamyl transpeptidase activity is high in about one-third of cases.2

The necropsy findings include a large, pale thrombus in the posterior vena cava between the liver and the right atrium. Occlusion of the posterior vena cava results in hepatomegaly and ascites. Hepatic abscesses of varying size and number are common and often near the wall of the thrombosed posterior vena cava.3 Pulmonary thromboembolism with multiple pulmonary abscesses, suppurative pneumonia and erosion of pulmonary arterial walls with intrapulmonary hemorrhage are also common. The lungs reveal emphysema, edema, and hemorrhage. A variety of bacteria including streptococci, E. coli, staphylococci and F. necrophorum are found in the abscesses in the liver.

Animals that die suddenly are found lying in a pool of blood and necropsy reveals large quantities of clotted blood in the bronchi and trachea.

The disease must be differentiated from verminous pneumonia, chronic aspiration pneumonia, pulmonary endarteritis due to endocarditis, and chronic atypical interstitial pneumonia. There is no treatment that is likely to have any effect on the disease and the principal task is to recognize the disease early and slaughter the animal for salvage if possible.

REFERENCE

CRANIAL VENA CAVAL THROMBOSIS

Thrombosis of the cranial vena cava occurs in cows.3 Cases in young animals are also recorded and it is suggested that they arise from navel infection. Clinical signs include cough, tachypnea, muffled heart sounds, exercise intolerance, and excessive pleural fluid. As in caudal vena caval thrombosis a number of pulmonary abscesses develop. Pulmonary hypertension is not a feature as it is in the caudal lesion. However, increased jugular vein pressure, dilatation of the jugular vein and local edema may all occur. Ultrasonography can reveal thrombosis of the cranial vena cava extending into the right atrium.3

REFERENCE

PULMONARY ABSCESS

The development of single or multiple abscesses in the lung causes a syndrome of chronic toxemia, cough, and emaciation. Suppurative bronchopneumonia may follow.

ETOLOGY

Pulmonary abscesses may be part of a primary disease or arise secondarily to diseases in other parts of the body.

Primary diseases
- R. equi pulmonary abscesses of foals1
- S. zooepidemicus and Actinobacillus sp. in adult horses.2 One-third of infectious causes of abscesses in horses are polymicrobial, and anaerobic bacteria are isolated in 20% of cases2
- Sequestration of an infected focus, e.g. strangles in horses, caseous lymphadenitis in sheep
- Tuberculosis
- Actinomycosis rarely occurs as granulomatous pulmonary lesions
- Aerogenous infections with ‘systemic’ mycoses, e.g. coccidioidomycosis, aspergillosis, histoplasmosis, cryptococcosis, and moniliasis
- Helicobacter ovis in horses
- Mycoplasma bovis in cattle.

Secondary diseases
- Sequestration of an infected focus of pneumonia, e.g. bovine pleuropneumonia or pleuropneumonia in horses
- Pulmonary abscesses secondary to ovine estrus3
- Emboli from endocarditis, caudal or cranial vena caval thrombosis, metritis, mastitis, omphalophlebitis
- Aspiration pneumonia from milk fever in cows, drenching accident in sheep – residual abscess
- Penetration by foreign body in traumatic reticuloperitonitis.

PATHOGENESIS

Pulmonary abscesses may be present in many cases of pneumonia and are not recognizable clinically. In the absence of pneumonia, pulmonary abscess is usually a chronic disease, clinical signs being produced by toxemia rather than by interference with respiration. However, when the spread is hematogenous and large numbers of small abscesses develop simultaneously, tachypnea occurs. In these animals the respiratory embarrassment cannot be explained by the reduction in vital capacity of the lung. However, in more chronic cases the abscesses may reach a tremendous size and cause respiratory difficulty by obliteration of large areas of lung tissue. In rare cases, erosion of a pulmonary vessel may occur, resulting in pulmonary hemorrhage and hemoptyis.

In many cases there is a period of chronic illness of varying degree when the necrotic focus is walled off by connective tissue. Exposure to environmental stress or other infection may result in a sudden extension from the abscess to produce a fatal, suppurative bronchopneumonia, pleurisy, or empyema.

CLINICAL FINDINGS

In typical cases there is dullness, anorexia, emaciation and a fall in milk yield in cattle. The temperature is usually moderately elevated and fluctuating. Coughing is marked. The cough is short and harsh and usually not accompanied by signs of pain. Intermittent episodes of bilateral epistaxis and hemoptyis may occur, which may terminate in fatal pulmonary hemorrhage following erosion of an adjacent large pulmonary vessel. Respiratory signs are variable depending on the size of the lesions, and although there is usually some increase in the rate and depth this may be so slight as to escape notice. When the abscesses are large (2–4 cm in diameter) careful auscultation and percussion will reveal the presence of a circumscribed area of dullness over which no breath sounds are audible. Crackles are often audible at the periphery of the lesion.

Multiple small abscesses may not be detectable on physical examination but the dyspnea is usually more pronounced. There may be a purulent nasal discharge and fetid breath but these are unusual unless bronchopneumonia has developed from extension of the abscess. Radiographic examination can be used to detect the presence of the abscess and give some information on its size and location.1

Most cases progress slowly and many affected animals have to be euthanized because of chronic ill-health; others die from bronchopneumonia or emphysema. Persistent fever, tachycardia, and polypnea are common. A rare sequel is the development of hypertrophic pulmonary osteoarthropathy.

The clinical findings of R. equi pulmonary abscessation in young foals are presented under that disease.

Solitary lung abscesses are not uncommon in adult horses. Presenting signs are usually low-grade fever and depression. Most horses with lung abscesses cough. There is excessive mucopurulent material in the trachea and examination of a tracheal aspirate reveals neutrophilic inflammation. Radiographic examination of the chest demonstrates the presence of one or more abscesses. Abscesses are in the caudal lung lobes in 60% of cases.2 Ultrasonography can be useful in detecting the abscess provided that it is confluent with the visceral pleura. The
prognosis for life and for return to racing is excellent in horses that are treated appropriately.2

CLINICAL PATHOLOGY
Examination of nasal or tracheal mucus may determine the causative bacteria but culture of tracheal swabs is difficult. Examination of nasal or tracheal mucus appropriately.2

Examination of nasal or tracheal mucus may determine the causative bacteria but culture of tracheal swabs is difficult. Examination of nasal or tracheal mucus is necessary. Treatment of pulmonary abscesses in adult horses by administration of broad-spectrum antimicrobials is usually effective.1,2 Most (> 80%) racehorses with single abscesses return to racing.2

There is a report of diagnosis of pulmonary abscess and bronchopneumonic fistula in a filly by thoracoscopy and partial pneumonectomy.5 The unusual feature of this case was the presence of a bronchopneumonic fistula that necessitated surgical correction. As noted above, almost all horses with solitary pulmonary abscesses recover with antimicrobial therapy.

PULMONARY AND PLEURAL NEOPLASMS
Primary neoplasms of the lungs, including carcinomas and adenocarcinomas, are rare in animals and metastatic tumors also are relatively uncommon in large animals. Primary tumors reported in lungs or pleura of the farm animal species include:

- Horses:
  - Granular cell tumors are the most common tumor arising in the pulmonary tissue of horses
  - Malignant melanomas in adult gray horses
  - Pulmonary adenocarcinoma (either primary or as metastatic disease)
  - Pulmonary leiomyosarcoma
  - Bronchogenic carcinoma, pulmonary carcinoma, bronchogenic squamous cell carcinoma, pulmonary chondrosarcoma and bronchial myxoma are all rare tumors in lungs of horses
  - Mesothelioma arise from the visceral or parietal pleura

- Cattle:
  - Pulmonary adenocarcinoma is the most commonly reported primary lung tumor in cattle.6 The ultrastructure and origin of some of these have been characterized
  - Lymphomatosis in young cattle may be accompanied by pulmonary localization

- Sheep:
  - Ovine pulmonary adenocarcinoma (jaagsieke sheep retrovirus)
  - Goats:
    - An asymptomatic, squamous-cell type tumor, thought to be a benign papilloma, has been observed in 10 of a series of 1600 adult Angora goats. The lesions were mostly in the diaphragmatic lobes, were multiple in 50% of the cases and showed no evidence of malignancy, although some had necrotic centers.

A wide variety of tumors metastasize to the lungs and these tumors can originate in almost any tissue or organ. A series of thoracic neoplasms in 38 horses included lymphosarcoma, metastatic renal cell carcinoma, primary lung carcinomas, secondary cell carcinoma from the stomach, pleural mesothelioma, and malignant melanoma.3

The etiology of the tumors is unknown in most cases, apart from those arising from viral infections. Equine granular cell tumors arise from the Swann cells of the peripheral nervous system in the lungs.4

Characteristically, primary pulmonary or pleural tumors arise in middle-aged to old animals. The prevalence of these tumors is well documented, although they are rare in abattoir studies of horses.5 The tumors occur sporadically, with the exception of those associated with infectious agents (bovine lymphomatosis, ovine pulmonary adenocarcinoma).

The pathogenesis of pulmonary tumors includes impairment of gas exchange, either by displacement of normal lung tissue by tumor tissue and surrounding atelectasis and necrosis, or obstruction of the large airways (e.g. granular cell tumor in horses).

CLINICAL FINDINGS
Clinical findings are those usually associated with the decrease in vital capacity of the lungs and include dyspnea that develops gradually, cough and evidence of local consolidation on percussion and auscultation. There is no fever or toxemia and a neoplasm may be mistaken for a chronic, encapsulated pulmonary abscess. Major clinical findings included weight loss, inappetence, and dyspnea and coughing. An anaplastic small-cell carcinoma of the lung of a 6-month-old calf located in the anterior thorax caused chronic bloating anorexia, and loss of body weight.6 Some tumors, notably mesothelioma and adenocarcinoma, cause accumulation of pleural fluid.7,8 Hypertrophic pulmonary osteopathy occurs in some animals with pulmonary tumors.5

Granular cell tumors in horses present as chronic coughing and exercise intolerance in horses without signs of infectious disease.10 As the disease progresses there is increased respiratory distress and uncontrolled coughing. It is often difficult to determine the precise location of the involvement of the lungs, but a chronic cough and severe dyspnea may be associated with the presence of a neoplasm. The course of the disease is usually chronic but may be acute, depending on the extent of the involvement of the lungs. The survival time of the animal is variable, ranging from months to years. The prognosis is generally poor, but may be improved by prompt treatment and adequate nutrition. The treatment of choice is surgical removal of the tumor, if possible, or radiotherapy. The use of chemotherapy is limited, and has not been very successful in these cases. The outcome of the treatment depends on the size of the tumor and the number of metastases. In some cases, the tumors may respond to treatment, but in most cases, the disease progresses and eventually results in death.
rate and effort and weight loss, suggestive of severe heaves. However, horses are unresponsive to treatment for heaves. The disease can progress to cor pulmonale and right-sided heart failure. A bronchial mass is evident on radiographic or endoscopic examination. There are no characteristic hematologic or serum biochemical changes.

Hemangiosarcomas of the thoracic cavities of horses occur and are evident as excess pleural fluid with a high red blood cell count.11,12

Thymoma, or lymphosarcoma as a part of the disease bovine viral leukosis, is not uncommon in cattle and may resemble pulmonary neoplasm but there is usually displacement and compression of the heart, resulting in displacement of the apex beat and congestive heart failure. The presence of jugular engorgement, ventral edema, tachycardia, chronic tympany, and hydropericardium may cause a mistaken diagnosis of traumatic pericarditis. Mediastinal tumor or abscess may have a similar effect. Metastasis to the bronchial lymph nodes may cause obstruction of the esophagus with dysphagia, and in cattle chronic ruminal tympany. This tumor is also common in goats, many of which show no clinical illness.

Radiographic or ultrasonographic examination is useful in demonstrating the presence of a mass in the lungs or thorax.13 Endoscopic examination is useful for detection of tumors that invade the larger airways, such as granular cell tumors of horses. Thoracoscopy and pleural biopsy can be useful in the diagnosis of lesions at the pleural surfaces.8

The nature of the tumor can sometimes be determined by examination of pleural fluid, into which some tumors shed cells, or of tumor tissue obtained by biopsy. Examination of pleural fluid for the presence of tumor cells is not very sensitive as many tumors do not shed sufficient numbers of cells to be detectable, but is quite specific in that detection of abnormal cells is diagnostic.

TREATMENT
There is no effective treatment with the exception of resection of localized tumors. Granular cell tumors in horses have been successfully treated by lung resection14 or transendoscopic electrocautery.15

Diseases of the pleura and diaphragm

HYDROTHORAX AND HEMOTHORAX

The accumulation of edematous transudate or whole blood in the pleural cavities is manifested by respiratory embarrassment caused by collapse of the ventral parts of the lungs.

ETIOLOGY
Hydrothorax and hemothorax occur as part of a number of diseases.

Hydrothorax
- As part of a general edema due to congestive heart failure or hypoproteinemia
- As part of African horse sickness or bovine viral leukosis
- Chylous hydrothorax, very rarely due to ruptured thoracic duct
- Secondary to thoracic neoplasia
- Yellow wood (Terminalia oblongata) poisoning of sheep
- Dilated cardiomypathy of Holstein–Friesian cattle.1

Hemothorax
- Traumatic injury to thoracic wall, a particular case of which is rib fractures in newborn foals2
- Hemangiosarcoma of pleura
- Lung biopsy
- Strenuous exercise by horses.3

PATHOGENESIS
Accumulation of fluid in the pleural cavities causes compression atelectasis of the ventral portions of the lungs and the degree of atelectasis governs the severity of the resulting dyspnea. Compression of the atria by fluid may cause an increase in venous pressure in the great veins, decreased cardiac return and reduced cardiac output. Extensive hemorrhage into the pleural space can cause hemorrhagic shock.

CLINICAL FINDINGS
In both diseases there is an absence of systemic signs, although acute hemorrhagic anemia may be present when extensive bleeding occurs in the pleural cavity. There is dyspnea, which usually develops gradually, and an absence of breath sounds, accompanied by dullness on percussion over the lower parts of the chest. In thin animals the intercostal spaces may be observed to bulge. If sufficient fluid is present it may cause compression of the atria and engagement of the jugular veins, and a jugular pulse of increased amplitude may be present. The cardiac embarrassment is not usually sufficiently severe to cause congestive heart failure, although this disease may already be present.

The accumulation of pleural fluid or blood is evident on radiographic or ultrasonographic examination of the thorax. Large quantities of blood in the pleural cavity have a characteristic swirling, turbulent appearance.

CLINICAL PATHOLOGY
Thoracentesis may yield a flow of clear serous fluid in hydrothorax, or blood in recent cases of hemothorax. The fluid is bacteriologically negative and total nucleated cell counts are low (<5 x 10⁹/L, < 5000 x 10⁹/L). The pH, Pco₂, and lactate and glucose concentrations of pleural fluid in animals with hydrothorax are similar to those of blood.

NECROPSY FINDINGS
In animals that die of acute hemorrhagic anemia resulting from hemothorax, the pleural cavity is filled with blood, which usually has not clotted, the clot having been broken down by the constant respiratory movement. Hydrothorax is not usually fatal but is a common accompaniment of other diseases, which are evidenced by their specific necropsy findings.

DIFFERENTIAL DIAGNOSIS

Hydrothorax and hemothorax can be differentiated from pleurisy by the absence of pain, toxemia and fever and by the sterility of an aspirated fluid sample.

TREATMENT
Treatment of the primary condition is necessary. If the dyspnea is severe, aspiration of fluid from the pleural sac causes a temporary improvement but the fluid usually reaccumulates rapidly. Parenteral coagulants and blood transfusion are rational treatments in severe hemothorax.

PNEUMOTHORAX
Pneumothorax refers to the presence of air (or other gas) in the pleural cavity. Entry of air into the pleural cavity in sufficient quantity causes collapse of the lung and impaired respiratory gas
exchange with consequent respiratory distress.

ETIOLOGY
Pneumothorax is defined as either spontaneous, traumatic, open, closed, or tension. Spontaneous cases occur without any identifiable inciting event. Open pneumothorax describes the situation in which gas enters the pleural space other than from a ruptured or lacerated lung, such as through an open wound in the chest wall. Closed pneumothorax refers to gas accumulation in the pleural space in the absence of an open chest wound. Tension pneumothorax occurs when a wound acts as a one-way valve, with air entering the pleural space during inspiration but being prevented from entering the pleural space during expiration by a valve-like action of the wound margins. The result is a rapid worsening of the pneumothorax. The pneumothorax can be unilateral or bilateral. The complete mediastinum of most cattle and horses means that in most instances the pneumothorax is unilateral, provided that the leakage of air into the pleural space occurs on only one side of the chest.

Rupture of the lung is a common cause of pneumothorax and can be either secondary to thoracic trauma, for example a penetrating wound that injures the lung, or lung disease. Most cases of pneumothorax in cattle are associated with pulmonary disease, notably broncho-pneumonia and interstitial pneumonia.1 Pleuropneumonia is the most common cause of pneumothorax in horses.2 Pneumothorax in these instances results from 'spontaneous' rupture of weakened lung or development of bronchopleural fistula.

Trauma to thoracic wall can lead to pneumothorax when a wound penetrates the thoracic wall, including the parietal pleura. In cattle, the thoracic wall may be punctured accidentally by farm machinery being used around cattle, for example when bales of hay are being moved among animals. Penetrating wounds of the thoracic wall are common causes in horses that impale themselves on fence posts and other solid objects.3 A special case of perforating lung injury occurs in newborns in which the rib is fractured during birth and the lung lacerated by the sharp edges of the fractured rib.4 Bullet and arrow wounds to the chest are not uncommon causes of pneumothorax in regions in which hunting is common.

Pneumothorax also occurs during thoracotomy, thoracoscopy or drainage of pleural or pericardial fluid. Pneumothorax can result from injury or surgery to the upper respiratory tract, presumably because of migration of air around the trachea into the mediastinum and subsequent leakage into the pleural space.5,6 Similarly, subcutaneous emphysema leads to pneumothorax via the mediastinum.6

PATHOGENESIS
Entry of air into the pleural cavity results in collapse of the lung. There can be partial or complete collapse of the lung. Collapse of the lung results in alveolar hypoventilation, hypoxemia, hypercapnia, cyanosis, dyspnea, anxiety, and hyper-resonance on percussion of the affected thorax. Tension pneumothorax can also lead to a direct decrease in venous return to the heart by compression and collapse of the vena cava.

The degree of lung collapse varies with the amount of air that enters the cavity; small amounts are absorbed very quickly but large amounts may cause fatal anoxia.

CLINICAL FINDINGS
There is an acute onset of inspiratory dyspnea, which may terminate fatally within a few minutes if the pneumothorax is bilateral and severe. If the collapse occurs in only one pleural sac, the rib cage on the affected side collapses and shows decreased movement. There is a compensatory increase in movement and bulging of the chest wall on the unaffected side. On auscultation of the thorax, the breath sounds are markedly decreased in intensity and commonly absent. The mediastinum may bulge toward the unaffected side and may cause moderate displacement of the heart and the apex beat, with accentuation of the heart sounds and the apex beat. The heart sounds on the affected side have a metallic note and the apex beat may be absent. On percussion of the thorax on the affected side, a hyperresonance is detectable over the dorsal aspects of the thorax.

Affected animals are anxious, tachypneic and in variable degrees of respiratory distress. Because many cases of pneumothorax in cattle and horses are secondary to lung disease, particularly infectious lung disease, there are usually signs of the inciting disease, including fever, toxemia, purulent nasal discharge and cough. Pneumothorax secondary to chest wall trauma is usually readily apparent, although fractured ribs that lacerate the lung and cause pneumothorax or hemothorax can be easily missed on physical examination, especially in newborns.

Definitive diagnosis is based on demonstration of pneumothorax by radiographic or ultrasonographic examination. Radiography permits the detection of bilateral and unilateral pneumothorax and permits identification of other air leakage syndromes, including pneumoneumediastinum, pneumoperitoneum, and pneumopericardium.1,7 Many cattle with pneumonia and pneumothorax have radiographic evidence of emphysematous bullae.1 Ultrasonography is also useful in determining the extent of pneumothorax and the presence of consolidated lung and pleural fluid.

Complications of pneumothorax, other than respiratory distress and death, include septic pleuritis secondary to contamination of the pleural space, either secondary to trauma or from ruptured infected lung.

The prognosis depends on the underlying disease and its severity. Of 30 cattle with pneumothorax, mostly secondary to pneumonia, 18 survived, eight were euthanized and four died.6 Of 40 horses with pneumothorax, 23 survived, 12 were euthanized and five died.6 The prognosis is better for animals with traumatic pneumothorax or that secondary to surgery than for animals with pneumothorax due to pneumonia.1,7

CLINICAL PATHOLOGY
Hematological and serum biochemical values are indicative of the underlying or concurrent disease – pneumothorax causes no specific changes in these variables. Arterial blood gas analysis reveals hypoxemia and hypercapnia.

NECROPSY FINDINGS
The lung in the affected sac is collapsed. In cases where spontaneous rupture occurs there is discontinuity of the pleura, usually over an emphysematous bulla. Hemothorax may also be evident.

DIFFERENTIAL DIAGNOSIS
The clinical findings are usually diagnostic. Diaphragmatic hernia may cause similar clinical signs but is relatively rare in farm animals. In cattle, herniation is usually associated with traumatic reticulitis and is not usually manifested by respiratory distress. Large hernias with entry of liver, stomach, and intestines cause respiratory embarrassment, a tympanic note on percussion and audible peristaltic sounds on auscultation.

TREATMENT
The treatment depends on the cause of the pneumothorax and the severity of the respiratory distress and hypoxemia. Animals should receive treatment for the underlying disease. Animals with closed pneumothorax that are not in respiratory distress or hypoxemic do not require specific treatment for the pneumothorax although the animal should be confined and prevented from exercising until the signs of pneumothorax have resolved. An open pneumothorax, due to a thoracic wound, should be surgically closed.
Emergency decompression of the pleural cavity using a needle into the pleural cavity, connected to a tubing and submerged into a flask of saline or water, creates a water-seal drainage. Thoracotomy tubes attached to Heinrich thoracic drainage valves are effective in preventing aspiration of air. Continuous suction, using thoracotomy (e.g. 24 French, 40 cm (16 in) Argyle trocar thoracic catheter) and a standard three-bottle water seal drainage system or commercial equivalent is preferable if there are large continuing air leaks that may be life-threatening. Reimplantation of the lung can be monitored by repeated ultrasonic examination. The animal should be kept as quiet as possible and permitted no exercise. Prophylactic antimicrobial treatment is advisable to avoid the development of pleurisy.

DIAPHRAGMATIC Hernia

Diaphragmatic hernia is uncommon in farm animals. It occurs in cattle, especially in association with traumatic reticuloperitonitis, in which case the hernia is small and causes no respiratory distress and there may be no abnormal sounds in the thorax. Diaphragmatic hernias in horses are usually traumatic, in that there is a tear in the diaphragm, although a specific traumatic episode is not always identified. Collision with a motor vehicle can cause diaphragmatic hernia in horses. The disease is reported in a gelding after steeplechase racing and can occur in mares during or after parturition.

Clinical findings

Clinical findings include chronic or recurrent ruminal tympany caused by herniation of reticulum preventing its normal function in eructation. Muffled heart sounds may be detectable on both sides of the thorax.

Occasional cases of acquired hernia not caused by foreign body perforation also occur in cattle and horses.

Some of the acquired diaphragmatic hernias in the horse are of long duration with an additional factor, such as the passage of a stomach tube or transportation, precipitating acute abdominal pain. In a case of traumatic hernia in a foal, a lack of exercise tolerance was the only clinical sign. Colic and dyspnea may occur as prominent clinical findings and usually as acute episodes. In some there is a history of recent thoracic trauma, although this can be severe months previously. Affected horses may have one or all of the following: tachypnea, painful or forced respirations. Colic can be sudden and severe but is usually preceded by intermittent episodes in the preceding days to months. The colic is a severe one, with the herniated intestine likely to become ischemic and necrotic. All the indications for exploratory laparotomy may be present except that the rectal findings are negative. Although the intestine may be incarcerated, abdomenoesinensis is likely to be negative but blood-stained fluid is present in the thoracic cavity. Clinical signs suggesting that the blood supply to the herniated intestine is compromised, but which are not accompanied by abnormal peritoneal fluid, suggest that the lesion is in the thorax, scrotum, or omental bursa.

The presence of intestinal sounds in the thorax can be misleading; they are often present in the normal animal but their presence, accompanied by dyspnea and resonance on percussion, should arouse suspicion. Radiography, ultrasonography, thoracoscopy and exploratory laparotomy are the most useful diagnostic procedures. Radiography reveals the presence of gas- and fluid-filled intestinal contents in the thorax, apparent in cattle as oval rounded masses over the heart. Ultrasonography demonstrates presence of bowel in the thorax. There can be excessive pleural fluid.

Congenital hernias occur in all species and the defects are usually large, are in the dorsal tendinous part of the diaphragm and have thin edges. Because of the large size of the defect, much of the abdominal viscera, including liver, stomach and intestines, enters the thorax and dyspnea is evident at birth. In some cases the pericardial sac is incomplete and the diaphragm is rudimentary and in the form of a small fold projecting from the chest wall. Affected animals usually survive for a few hours to several weeks. In pigs a number of animals in each litter may be affected. Surgical repair has been performed in neonates, and successful surgical intervention is recorded in one horse, but the prognosis is usually poor.

The definitive treatment of acquired or traumatic hernia is surgical replacement of viscera in the abdomen and repair of the defect in the diaphragm. Repair of a diaphragmatic hernia through a standing thoracotomy in a cow has been described.

Synchronous Diaphragmatic Flutter in Horses (Thumps)

Synchronous diaphragmatic flutter in horses is caused by an abrupt and powerful contraction of the diaphragm synchronous with the heart beat. Contraction of the diaphragm occurs because of stimulation of the phrenic nerve as it passes over the atria of the heart. Thumps is often associated with electrolyte abnormalities in horses. The disease occurs commonly in horses used for strenuous exercise, and in particular horses used for endurance racing. The disease occurs in Standardbred and Thoroughbred race horses, and individual animals can be affected repeatedly. This disease also occurs sporadically in adult horses and ponies that have not exercised, and peripartum mares (lactation tetany).

The syndrome is characterized by a violent hicccough occurring synchronously with every heart beat. The lateral aspect of the thorax and cranial abdomen appear to jump or 'thump' regularly in affected horses. It is often unilateral, the contraction being felt very much more strongly on one side than the other. The horse is distressed because the hiccough interferes with eating, and to an extent with respiration. In some cases there are additional signs suggestive of hypocalcemia. These include muscular rigidity and fasciculation, and a high-stepping gait. There is often hypocalcemia, hyperkalemia, alkalosis and hypokalemia, hypochloremia and elevation of creatine phosphokinase levels in affected horses. Hypocalcemia can be profound. The disease is reported as a consequence of hypocalcemia secondary to primary hypoparathyroidism in two Thoroughbred horses.

The principles of treatment are correction of abnormalities in blood electrolyte concentration and hydration. Treatment with calcium borogluconate slowly and intravenously has been followed by rapid recovery in many cases. Some horses require administration of balanced isotonic polyionic electrolyte solutions intravenously (e.g. Ringer’s solution or 0.9% sodium chloride).

The pathogenesis is thought to be related to hyperirritability of the phrenic nerve caused by metabolic disturbances, including hypocalcemia, and the phrenic nerve being stimulated by each atrial depolarization to fire with each heart beat. The stimulation occurs because of the close physical proximity of the heart to the nerve in the horse. Dietary supplementation with calcium and other...
electrolytes during a ride is recommended but excessive calcium feeding beforehand may reduce the activity of calcium homeostatic mechanisms, and is to be avoided.

Regular veterinary inspection of all horses at the mandatory stops of endurance rides will reveal those animals with 'thumps', which should not be allowed to proceed in the event.

REFERENCE

PLEURITIS (PLEURISY)

Pleuritis refers to inflammation of the parietal and visceral pleura. Inflammation of the pleura almost always results in accumulation of fluid in the pleural space. Pleuritis is characterized by varying degrees of toxaemia, painful shallow breathing, pleural friction sounds and dull areas on auscultatory percussion of the thorax because of pleural effusion. Treatment is often difficult because of the diffuse nature of the inflammation.

ETIOLOGY

Pleuritis is almost always associated with diseases of the lungs. Pneumonia can progress to pleuritis, and pleuritis can cause consolidation and infection of the lungs. Primary pleuritis is usually due to perforation of the pleural space and subsequent infection. Most commonly this occurs as a result of trauma, but it can occur in cattle with traumatic reticulo-peritonitis and in any species after perforation of the thoracic esophagus. Secondary pleuritis refers to that which develops from infectious lung disease subsequent to the following conditions.

Pigs
- Glasser's disease
- Pleuropneumonia associated with Actinobacillus (Haemophilus) pleuropneumoniae and Haemophilus influenzae suis
- The prevalence of pneumonia and pleurisy in pigs examined at slaughter represents a significant loss in production.

Cattle
- Secondary to Mannheimia haemolytica pneumonia in cattle, especially feedlot cattle, which may be related to a high percentage of fibrotic pleural lesions found in adult cattle examined at the abattoir
- Tuberculosis
- Sporadic bovine encaphalomyelitis
- Contagious bovine pleuropneumonia
- Histophilus somnus infection
- Pleural lesions are common in veal calves examined at slaughter.

Sheep and goats
- Pleuropneumonia associated with Mycoplasma spp., including Mycoplasma mycoides subsp. mycoides and Haemophilus spp.
- Streptococcus dysgalactiae in ewes.

Horses
The disease in horses is discussed separately in the next section. Rare causes of pleurisy and pleural effusion in horses include lymphosarcoma and equine infectious anemia. Mediotholimia of the pleura causing persistent dyspnea, pleural effusion and death is also recorded in the horse. Thoracic hemangiosarcoma is recorded as a cause of chylothorax in the horse.

Other causes
- Sporadic and nonspecific diseases may be accompanied by pleurisy. Examples include septicaemias due to Pseudomonas aeruginosa; bacteremia with localization causing a chronic septic pleural effusion. In horses, the infection is usually S. equi and the original disease is strangles. In goats, it is usually spread from a mycoplasmal pneumonia.
- Perforation of the diaphragm occurs in traumatic reticuloperitonitis in cattle and goats. Spread into the pleural cavity can occur without actual penetration of the diaphragm, as it enters via the lymphatics. Abomasopleural fistula secondary to abomasal ulceration can cause pleuritis in cattle.
- Chronic pleuritis is an important cause of loss in commercial piggeries. The prevalence can be as low as 5.6% of pigs at slaughter in specific-pathogen-free piggeries and as high as 27% in conventional piggeries.

PATHOGENESIS

Contact and movement between the parietal and visceral pleura causes pain due to stimulation of pain end organs in the pleura. Respiratory movements are restricted and the respiration is rapid and shallow. There is production of serofibrinous inflammatory exudate, which collects in the pleural cavities and causes collapse of the ventral parts of the lungs, thus reducing vital capacity and interfering with gaseous exchange. If the accumulation is sufficiently severe there may be pressure on the heart and diminished return of blood to the heart. Clinical signs may be restricted to one side of the chest in all species with an imperforate mediastinum. Fluid is resorbed in animals that survive the acute disease and adhesions develop, restricting movement of the lungs and chest wall but interference with respiratory exchange is usually minor and disappears gradually as the adhesions stretch with continuous movement.

In all bacterial pleuritis, toxemia is common and usually severe. The toxemia may be severe when large amounts of pus accumulate.

CLINICAL FINDINGS

The clinical findings of pleuritis vary from mild to severe. Depending on the species and the nature and severity of the inflammation, in peracute to acute stages of pleuropneumonia there are fever, toxemia, tachycardia, anorexia, depression, nasal discharge, coughing, exercise intolerance, breathing distress, and flared nostrils. The nasal discharge depends on the presence or absence of pneumonia. It may be absent or copious and its nature may vary from mucopurulent to mucopurulent. The odor of the breath may be putrid, which is usually associated with an anaerobic lesion.

Pleural pain
Pleural pain (pleurodynia) is common and manifested as pawing, stiff forelimb gait, abducted elbows and reluctance to move or lie down. In the early stages of pleuritis, breathing is rapid and shallow and markedly reduced and movement of the thoracic wall is restricted. The breathing movements may appear guarded, along with a catch at end-inspiration. The animal stands with its elbows abducted and is disinclined to move. The application of hand pressure on the thoracic wall and deep digital palpation of intercostal spaces usually causes pain manifested by a grunt, a spasm of the intercostal muscles or an escape maneuver.

Pleuritic friction sounds
These may be audible over the thoracic wall. They have a continuous to-and-fro character, are dry and abrasive, and do not abate with coughing. They may be difficult to identify if there is a coincident pneumonia accompanied by loud breath sounds and crackles. When the pleuritis involves the pleural surface of the pericardial sac a friction rub may be heard with each cardiac cycle and be confused with the friction sound of pericarditis. However, there is usually in addition a friction sound synchronous with respiratory movements and the pericardial rub waxes and wanes with expiration and inspiration. Pleural friction rubs are audible only during the initial stages of the disease - they are not audible when fluid accumulates in the pleural space.

Subcutaneous edema
Subcutaneous edema of the ventral body wall extending from the pectorals to the prepubic area is common in horses with severe pleuritis but is less noticeable in other species. Presumably this edema is due to blockage of lymphatics normally drained through the sternal lymph nodes.
Pleural effusion

In cattle, an inflammatory pleural effusion is often limited to one side because the pleural sacs do not communicate. Bilateral pleural effusion may indicate either a bilateral pulmonary disease process or a noninflammatory abnormality such as right-sided congestive heart failure or hypoproteinemia.

Dullness on acoustic percussion over the fluid-filled area of the thorax is characteristic of pleuritis in which there is a significant amount of pleural effusion. The dull area has a horizontal level topline, called a fluid line, which can be demarcated by acoustic percussion. As exudation causes separation of the inflamed pleural surfaces and the pleural effusion accumulates, the pain and friction sounds diminish but do not completely disappear. On auscultation there may still be pleuritic friction sounds but they are less evident and usually localized to small areas.

In the presence of a pleural effusion, both normal and abnormal lung sounds are diminished in intensity, depending on the amount of the effusion. Dyspnea may still be evident, particularly during inspiration, and a pleuritic ridge develops at the costal arch as a result of elevation of the ribs and the abdominal-type respiration. However, the degree of dyspnea is often subtle and careful clinical examination and counting of the breathing rate is necessary to detect the changes in breathing.

If the pleurisy is unilateral, movement of the affected side of the thorax is restricted as compared to the normal side. In cattle, the pleural effusion is commonly unilateral on the right side but both sides may be affected. Pain is still evident on percussion on deep palpation of the intercostal spaces and the animal still stands with its elbows abducted, is disinclined to lie down or move but is not as apprehensive as in the early stages. Toxemia is often more severe during this stage, the temperature and the heart rate are usually above normal and the appetite is poor. A cough will be present if there is a concurrent pneumonia and it is painful, short and shallow. Extension of the inflammation to the pericardium may occur. Death may occur at any time and is due to a combination of toxemia and anoxia caused by pressure atelectasis.

Recovery

Animals with pleuritis characteristically recover slowly over a period of several days or even weeks. The toxemia usually resolves first but abnormalities in the thorax remain for some time because of the presence of adhesions and variable amounts of pleural effusion in the loculi.

Rupture of the adhesions during severe exertion may cause fatal hemothorax. Some impairment of respiratory function can be expected to persist and racing animals do not usually regain complete efficiency. Chronic pleurisy, as occurs in tuberculosis in cattle and in pigs, is usually subclinical, with no acute inflammation or fluid exudation occurring.

Medical imaging

Radiographic examination may reveal the presence of a fluid line and fluid displacement of the mediastinum and heart to the unaffected side and collapse of the lung. However, in cattle, pleural effusion cannot be located precisely by radiography because only laterolateral radiographs of the thorax can be taken. Ultrasonography is superior for the visualization of small volumes of pleural fluid that cannot be detected by auscultation and acoustic percussion of the thorax. Ultrasound photography

Ultrasonography is more reliable for the detection of pleural fluid in horses and cattle than radiography. Pleural fluid is easily detected as hypoechoic to anechoic fluid between the parietal pleural surface, pneumothorax is minimized by the use of a purse string suture placed around the intercostal space just above the point of the shoulder. The lung will collapse but pneumothorax is minimized by the use of a purse string suture placed around the stab incision and blunt dissection of the fascia and muscle layers for insertion of the endoscope. The diaphragm, costopleural angle, aorta, mediastinal structures and thoracic wall are clearly visible. By

Fig. 10.2 Ultrasonogram and schematic of the thorax in a cow with pleuroneumonia due to infection with Mannheimia haemolytica. There is an accumulation of anechoic pleural effusion, which compresses the lung. The ultrasonogram was obtained from the distal region of the sixth intercostal space of the left thoracic wall with a 5.0 MHz linear scanner. 1 = Thoracic wall; 2 = Anechoic fluid; 3 = Lung. Ds, Dorsal; Vt, Ventral. (Reproduced with kind permission of U. Braun.)
entering the thorax at different locations, the ventral lung, the pericardium and more of the diaphragm can be visualized. Lung and pleural abscesses and pleural adhesions may be visible.

**Prognosis**
The prognosis depends on the severity and extent of the pleuritis and the presence of pneumonia. The presence of dull areas over the ventral two-thirds of the thorax on both sides and more than about 6 L of pleural fluid in the pleural cavity of a mature horse suggests an unfavorable prognosis. If the disease is in an advanced stage when first recognized and there is extensive fibrinous inflammation, the response to treatment can be protracted and extensive long-term daily care will be necessary. Also, the common failure to culture the primary causative agent, particularly in horses, makes specific therapy difficult.

**CLINICAL PATHOLOGY**
**Thoracentesis (pleurocentesis)**
Thoracentesis to obtain a sample of the fluid for laboratory examination is necessary for a definitive diagnosis. The fluid is examined for its odor, color, viscosity, protein concentration and presence of blood or tumor cells, and is cultured for bacteria. It is important to determine whether the fluid is an exudate or a transudate. Pleural fluid from horses with anaerobic bacterial pleuropneumonia may be foul-smelling. Examination of the pleural fluid usually reveals an increase in leukocytes up to 40,000–100,000/μL and protein concentrations of up to 50 g/L (5.0 g/dL). The fluid should be cultured for both aerobic and anaerobic bacteria and *Mycoplasma* spp.

**Hematology**
In peracute bacterial pleuropneumonia in horses and cattle, leukopenia and neutropenia with toxic neutrophils are common. In acute pleuritis with severe toxemia, hemocoagulation, neutropenia with a left shift and toxic neutrophils are common. In subacute and chronic stages normal to high leukocyte counts are often present. Hyperfibrinogenemia, decreased albumin–globulin ratio and anemia are common in chronic pleuropneumonia.

**Necropsy Findings**
In early acute pleurisy there is marked edema, thickening and hyperemia of the pleura, with engorgement of small vessels and the presence of tags and shreds of fibrin. These can most readily be seen between the lobes of the lung. In the exudative stage the pleural cavity contains an excessive quantity of turbid fluid containing flakes and clots of fibrin. The pleura is thickened and the central parts of the lung are collapsed and dark red in color. A concurrent pneumonia is usually present and there may be an associated pericarditis. In the later healing stages, adhesions connect the parietal and visceral pleura. Type I fibrinous adhesions appear to be associated with pneumonia while type II fibrinous proliferative adhesions are idiopathic.

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of pleuritis is confirmed by:
- The presence of inflammatory fluid in the pleural cavity
- Pleural friction sounds, common in the early stages of pleuritis and loud and abrasive; they sound very close to the surface, do not fluctuate with coughing common in the early stages and may continue to be detectable throughout the effusion stage
- The presence of dull areas and a horizontal fluid line on acoustic percussion of the lower aspects of the thorax, characteristic of pleuritis and the presence of pleural fluid
- Thoracic pain, fever and toxemia are common.

**Pneumonia** occurs commonly in conjunction with pleuritis and differentiation is difficult and often unnecessary. The increased intensity of breath sounds associated with consolidation and the presence of crackles and wheezes are characteristic of pneumonia.

**Pulmonary emphysema** is characterized by loud crackles, expiratory dyspnea, hyperresonance of the thorax and lack of toxemia unless associated with bacterial pneumonia.

**Hydrothorax** and **hemothorax** are not usually accompanied by fever or toxemia and pain and pleuritic friction sounds are not present. Aspiration of fluid by needle puncture can be attempted if doubt exists. A pleural effusion consisting of a transudate may occur in cor pulmonale due to chronic interstitial pneumonia in cattle.

**Pulmonary congestion and edema** are manifested by increased vesicular murmur and ventral consolidation without hydrothorax or pleural inflammation.

**TREATMENT**
The principles of treatment of pleuritis are pain control, elimination of infection and prevention of complications.

**Antimicrobial therapy**
The primary aim of treatment is to control the infection in the pleural cavities using the systemic administration of antimicrobials, which should be selected on the basis of culture and sensitivity of pathogens from the pleural fluid. Before the antimicrobial sensitivity results are available it is recommended that broad-spectrum antimicrobials be used. Long-term therapy daily for several weeks may be necessary.

**Drainage and lavage of pleural cavity**
Drainage of pleural fluid removes exudate from the pleural cavity and allows the lungs to re-expand. Criteria for drainage include:
- An initial poor response to treatment
- Large quantities of fluid causing respiratory distress
- Putrid pleural fluid
- Bacteria in cells of the pleural fluid.

Clinical experience suggests that drainage improves the outcome.

Pleural fluid can be drained using intermittent thoracentesis or indwelling chest tubes. Intermittent drainage is satisfactory in an animal with a small amount of fluid. Small (12–20 French) chest tubes are temporarily inserted at 2–3-day intervals to remove the fluid. Aspiration may not be easy in some cases where the drainage tube may become blocked with fibrin and respiratory movements may result in laceration of the lung. Drainage may be difficult or almost impossible in cases in which adhesion of visceral and parietal pleura are extensive and fluid is localized.

Indwelling chest tubes may be required unilaterally or bilaterally depending on the patency of mediastinal fenestration and the degree of fluid accumulation. A large bore (24–32 French) chest tube is inserted and secured to prevent it from sliding out. Unidirectional drainage through the tube is facilitated by a Heimlich valve and monitored regularly. Pleural fluid is allowed to drain or drip passively, since suction often results in obstruction of the tube with fibrin or peripheral lung tissue. Loculation of fluid may interfere with proper drainage and necessitate replacement of tubes. Complications include subcutaneous cellulitis or pneumothorax.

**Pleural lavage** may assist in removal of fibrin, inflammatory debris, and necrotic tissue; it can prevent loculation, dilute thick pleural fluid and facilitate drainage. One chest tube is placed dorsally and one ventrally; 5–10 L of sterile, warm isotonic saline is infused into each hemithorax by gravity flow. After infusion, the chest tube is reconnected to a unidirectional valve and the lavage fluid is allowed to drain.

**Thoracotomy** has been used successfully for the treatment of pericarditis and pleuritis and lung abscesses in cattle. Claims are made for the use of dexmethasone at 0.1 mg/kg BW to reduce the degree of pleural effusion. In acute cases of pleurisy in the horse analogues such as phenylbutazone are valuable to relieve pain and anxiety, allowing the horse to eat and drink more normally.
**Fibrinolytic therapy**

Pleural adhesions are unavoidable and may become thick and extensive with the formation of loculation which traps pleural fluid, all of which prevents full recovery. However, some animals will stabilize at a certain level of chronicity, will survive for long periods and may be useful for light work or as breeding animals. Fibrinolytic agents such as streptokinase have been used in human medicine to promote the thinning of pleural fluid, provide enzymatic debridement of the pleura, lyse adhesions and promote drainage of loculi. However, these have not been evaluated in farm animals with pleuritis.

**REFERENCES**

**EQUINE PLEUROPNEUMONIA (PLEURITIS, PLEURISY)**

**ETIOLOGY**

Pleuropneumonia of horses is almost always associated with bacterial infection of the lungs, pleura, and pleural fluid. The most common bacterial isolates from tracheal aspirates or pleural fluid of horses with pleuropneumonia are:

- Aerobic or facultative anaerobes including: *S. equi* var. *zooepidemicus*, *Pasteurella* spp., *Actinobacillus* spp., Enterobacteriaceae (particularly *E. coli*, *Klebsiella* spp., and *Enterobacter* spp.), *Pseudomonas* spp., *Staphylococcus* spp. and *Bordetella* spp. *S. zooepidemicus* is isolated from over 60%, Enterobacteriaceae from approximately 40% of cases, and *Pasteurella/Actinobacillus* spp. from approximately one-third of cases.1,2,3 *Corynebacterium pseudotuberculosis* can cause septic pericarditis and pleuritis, although this is an uncommon disease.3 *Mycoplasma fels* is an unusual cause of pleuritis in horses.4,5 *R. equi*, usually a cause of pneumonia in foals, rarely causes pleuropneumonia in immunocompetent adult horses.

- Obligate anaerobes, including *Bacteroides* spp. (including *B. fragilis* and *B. tectum*), *Prevotella* spp., *Clostridium* spp., *Eubacterium* and *Fusobacterium* spp.4,5 Bacteroides sp. are isolated from approximately 20%, *Clostridium* sp. from 10%, and *Eubacterium* sp. from 6% of horses with pleuropneumonia.4 Obligate anaerobes are cultured from approximately 70% of horses with severe pneumonia.5 Equine pleuropneumonia is associated with polymicrobial infections of the lungs and pleura in 50–80% of cases, although disease associated with infection with a single bacterial species occurs.6,7 Infections with a single bacterial species are usually by *S. zooepidemicus*, *Pasteurellial Actinobacillus* sp. or one of the Enterobacteriaceae, whereas almost all infections by anaerobes are polymicrobial.8 Infection by obligate anaerobic bacteria is associated with disease of more than 5–7 days' duration.9

Pleuritis is also caused by penetrating chest wounds,9 perforated esophagus,10 and thoracic neoplasia.11 Other diseases, such as congestive heart failure, may cause pleural effusion without inflammation.

**EPIDEMIOLOGY**

Pleuropneumonia occurs worldwide in horses of all ages and both sexes, although most cases occur in horses more than 1 and less than 5 years of age.12 Estimates of the incidence or prevalence of the disease are not available. The case fatality rate varies between 5% and 65%, with the higher rate reported in earlier studies.12,13

**Risk factors**

The risk of a horse developing pleuropneumonia is increased by a factor of:

- 4 if the horse is a Thoroughbred racehorse
- 14 if the horse was transported more than 500 miles in the previous week
- 10 if the horse has a recent (<2 week) history of viral respiratory tract disease or exposure to a horse with such disease
- 4 if the horse has raced within the previous 48 hours14

Other suggested risk factors include general anesthesia, surgery, disorders of the upper airway, exercise-induced pulmonary hemorrhage, esophageal obstruction, and dysphagia.

**PATHOGENESIS**

Bacterial pleuropneumonia develops following bacterial colonization of the lungs with subsequent extension of infection to the visceral pleura and pleural space.9 Organisms initially colonizing the pulmonary parenchyma and pleural space are those normally present in the upper airway, oral cavity, and pharynx, with subsequent infection by Enterobacteriaceae and obligate anaerobic bacteria.2

**Bacterial colonization** and infection of the lower airway is attributable to either massive challenge or a reduction in the efficacy of normal pulmonary defense mechanisms or a combination of these factors.9 Confinement with the head elevated for 12–24 hours, such as occurs during transport of horses, decreases mucociliary transport and increases the...
number of bacteria and inflammatory cells in the lower respiratory tract and probably contributes to the development of lower respiratory tract disease.\(^{14,15}\) **Transport** alters the composition of pulmonary surfactant, which can impair the activity of pulmonary defense mechanisms, allowing otherwise innocuous bacterial contamination to cause disease.\(^ {16,17}\)

Overwhelming bacterial challenge may occur in dysphagic horses, horses with esophageal obstruction and race horses that inhale large quantities of track debris while racing. A single bout of **exercise** on a treadmill markedly increases bacterial contamination of the lower airways.\(^ {18}\) Viral respiratory disease may decrease the efficacy of normal lung defense mechanisms.

**Bacterial multiplication** in pulmonary parenchyma is associated with the influx of inflammatory cells, principally neutrophils, tissue destruction and accumulation of cell debris in alveoli and airways. Infection spreads both through tissue and via airways. Extension of inflammation, and later infection, to the visceral pleura and subsequently pleural space causes accumulation of excess fluid within the pleural space. Pleural fluid accumulates because of a combination of excessive production of fluid by damaged pleural capillaries (exudation) and impaired reabsorption of pleural fluid by thoracic lymphatics.

**Accumulation of parapneumonic pleural effusions** has been arbitrarily divided into three stages: exudative, fibrinopurulent and organizational.\(^ {19}\)

1. **The exudative stage** is characterized by the accumulation of sterile, protein-rich fluid in the pleural space as a result of increased pleural capillary permeability
2. Bacterial invasion and proliferation, further accumulation of fluid, and deposition of fibrin in pleural fluid and on pleural surfaces occurs if the disease does not resolve rapidly and is referred to as the **fibrinopurulent stage**
3. **The organizational stage** is associated with continued fibrin deposition, restriction of lung expansion, and persistence of bacteria. The pleural fluid contains much cellular debris and bronchopleural fistulas may develop.

These categorizations are useful diagnostically and therapeutically.

**CLINICAL SIGNS OF ACUTE DISEASE**

The acute disease is characterized by the sudden onset of a combination of fever, depression, inappetence, cough, exercise intolerance, respiratory distress, and nasal discharge. The respiratory rate is usually elevated as is the heart rate.

**Nasal discharge** ranges from serosanguineous to mucopurulent, is usually present in both nares and is exacerbated when the horse lowers its head. The **breath may be malodorous**, although this is a more common finding in horses with subacute to chronic disease. Horses with pleuritis are often reluctant to cough and if they do, the cough is usually soft and gentle. Ventral edema occurs in approximately 50% of horses with pleuropneumonia.\(^3\)

The horse may appear **reluctant to move** or may exhibit signs of chest pain, including reluctance to move, pawing and anxious expression, which may be mistaken for colic, lamiinitis, or rhabdomyolysis. Affected horses often stand with the elbows abducted.

**Auscultation** of the thorax reveals attenuation of normal breath sounds in the ventral thorax in horses with significant accumulation of pleural fluid. However, the attenuation of normal breath sounds may be mild and difficult to detect, especially in large or fat horses or in horses in which there is only slight accumulation of pleural fluid. Auscultation of the thorax with the horse’s respiratory rate and tidal volume increased by having it breathe with a large airtight bag over its nostrils may reveal crackles and wheezes in the dorsal lung fields and attenuation of the breath sounds ventrally. There is often fluid in the trachea detectable as a tracheal rattle.

**Percussion** of the chest wall may reveal a clear line of demarcation below which the normal resonant sounds are muffled. This line of demarcation represents the dorsal limit of the pleural fluid. Both lung fields should be examined to identify localized areas of consolidation. Careful percussion of the thorax is a cheap and effective way of identifying the presence and extent of pleural fluid accumulation.

**Ultrasonographic examination** of the thorax is a very sensitive technique which demonstrates accumulation of pleural fluid, determine the character of the fluid, identify localized areas of fluid accumulation or pulmonary consolidation, identify sites for thoracocentesis and monitor response to treatment.\(^ {20,21}\) The examination is best performed using a 3.5–5.0 MHz sector scanner. Linear probes, such as those used for routine reproductive examination, are adequate to identify fluid but do not allow good examination of all areas of the chest accessible with sector scanners. The entire thorax should be examined in a systematic fashion. The presence of and characteristics of fluid within the pleural space, presence and location of pulmonary consolidation or abscessation and potential sites for diagnostic and therapeutic thoracocentesis should be identified. For horses with long-standing disease, the area cranial to the heart should be examined for the presence of cranial thoracic masses (abscesses). This examination requires that the horse’s isilateral forelimb be placed well forward, usually with the aid of an assistant, to allow adequate visualization of the cranial thorax.

- **Excessive pleural fluid** can be detected by thorough ultrasonographic examination of both hemithoraces. Pleural fluid initially accumulates ventrally in acute cases, but may become localized dorsal in chronic cases with seption of the pleural space and trapping of fluid
- The pleural fluid may contain small gas echoes, an indication of infection with anaerobic bacteria and a poor prognosis, strands of fibrin or echogenic material consistent with cellular debris. Sterile pleural effusion, such as may be present during the earliest stages of the disease, is clear and homogeneous without fibrin strands. With increasing chronicity the amount of fibrin increases, the parietal and visceral pleura become thickened, and the pleural fluid becomes echogenic consistent with cellular debris
- **Regions of consolidated or atelectatic lung** adjacent to the visceral pleura may be evident on ultrasonographic examination, but lung consolidation deeper in the lung is not evident
- Ultrasonography is more sensitive than radiographic examination in detection of small quantities of pleural fluid.\(^ {21}\)

**Radiographic examination** of horses with excessive pleural fluid reveals ventral opacity that obscures the ventral diaphragmatic and cardiac silhouettes. It is not possible on radiographic examination to differentiate accumulation of pleural fluid from consolidation of the ventral lung lobes.\(^ {21}\) Radiographic examination may be useful in demonstrating lesions, such as pulmonary abscesses or consolidation, that are not confluent with the visceral pleura and therefore not able to be detected by ultrasonographic examination.\(^ {21}\)

**Collection of pleural fluid** by thoracocentesis of both hemithoraces and of a tracheal aspirate is necessary to characterize the nature of the pleural fluid and determine the bacterial species present (see clinical pathology). Both
The chronic disease is characterized by pneumonia as bacteria may be recovered not useful in diagnosing pleuropneumonia in horses.\textsuperscript{12} The clinical course of the acute form of the disease may be less than 10 days if effective therapy is instituted before the pleural effusion becomes infected or there is substantial deposition of fibrin in the pleural space. The prognosis for a return to previous function is good in horses that respond. However, most cases, even if appropriate therapy is instituted, progress to at least stage 2 of the disease process and the disease becomes chronic.

**CLINICAL SIGNS IN CHRONIC DISEASE**

The chronic disease is characterized by intermittent fever, weight loss, cough, increased respiratory rate, nasal discharge, malodorous breath, exercise intolerance, and depression. Severely affected horses may display signs of respiratory distress. Signs of thoracic pain are less than in the acute disease.

Findings on auscultation of the chest are similar to those of the acute disease in as much as there is attenuation of normal breath sounds ventrally and the presence of cracks and wheezes dorsally. There is frequently ventral edema of the thorax.

**Ultrasoundographic** examination reveals the presence of excessive pleural fluid that is very echogenic, consistent with it containing cellular debris, and containing large amounts of fibrin. The visceral and parietal pleura are thickened and there may be evidence of lung atelectasis, consolidation, or abscessation. Septation of the pleural space by fibrin and fibrous tissue results in localized accumulation of purulent pleural fluid. Air in the pleural space may indicate the presence of one or more bronchopleural fistulae.

**Radiographic examination** reveals a combination of ventral opacity, pulmonary consolidation, pneumothorax, and abscessation.

**Complications**

Complications of pleuropneumonia include:

- Development of jugular thrombophlebitis (25% of cases)
- Pulmonary, mediastinal, or pleural abscesses (10–20% of cases)
- Cranial thoracic mass (5–10% of cases)
- Bronchopleural fistula (5%)
- Pericarditis (2%)
- Laminitis (1–14%).\textsuperscript{17-19}

Development of intrathoracic abscesses is evident as chronic disease, weight loss, cough and fever, readily detected by a combination of ultrasonographic and radiographic examination.

**Cranial thoracic masses** are evident as an elevation in heart rate, prominent jugular pulse, spontaneous jugular throbismosis, and forelimb pointing. The signs are referable to a mass in the cranial thorax displacing the heart caudally and to the left and impairing venous return to the heart in the cranial vena cava.\textsuperscript{23} Ultrasonographic and radiographic examination reveals the presence of the mass.

**Bronchopleural fistulae** develop when a section of pulmonary parenchyma sloughs, leaving an open bronchiol that communicates with the pleural space. Mild pneumothorax develops. The broncho­pleural fistula can be diagnosed by infusion of fluorescein dye into the pleural space and detecting its presence at the nares, or by pleuroscopic examination.\textsuperscript{24,26}

**Prognosis**

The prognosis for life for horses able to be treated aggressively is very good (60–95%\textsuperscript{13} and the prognosis for return to previous function if the horse survives is reasonable (60%).\textsuperscript{13} The prognosis for return to previous function for horses that develop chronic disease and complications is poor (31%).\textsuperscript{13}

**CLINICAL PATHOLOGY**

Acute pleuropneumonia is characterized by leukocytosis with a mature neutrophilia, mild to moderate anemia, hyperfibrinogenemia, and hypoalbuminemia.\textsuperscript{24} There are similar findings in horses with chronic disease and hyperglobulinemia is also usually present. Severely affected horses with acute disease often have hemococoncentration and azotemia.

**Pleural fluid** in acute cases is usually cloudy and red to yellow. It has an increased leukocyte number (> 10,000 cells/\textmu L, 10 × 10\textsuperscript{6} cells/L) comprised principally of degenerative neutrophils, an increased protein concentration (> 2.5 g/dL, 25 g/L) and may contain intracellular and extracellular bacteria.\textsuperscript{27} A Gram stain of the fluid should be examined. The pleural fluid should be cultured for aerobic and anaerobic bacteria. A putrid odor suggests infection by anaerobic bacteria. Sterile pleural fluid has a pH, PO\textsubscript{2} and PCO\textsubscript{2} and lactate, glucose and bicarbonate concentration similar to that of venous blood.\textsuperscript{28} Infected pleural fluid is acidic, hypercarbic and has an increased concentration of lactate and decreased concentrations of bicarbonate and glucose compared to venous blood.\textsuperscript{28}

**Tracheal aspirates** have a leukocytosis comprised of degenerate neutrophils with intra- and extracellular bacteria. Cultures of tracheal aspirates more frequently yield growth than do cultures of pleural fluid (90% v 66%).\textsuperscript{2}

**DIAGNOSTIC CONFIRMATION**

The presence of excessive pleural fluid containing bacteria and degenerate neutrophils in combination with clinical signs of respiratory disease provides confirmation of the disease.

**DIFFERENTIAL DIAGNOSIS**

Diseases that may cause respiratory distress and pleural effusion in horses include:

- Intrathoracic neoplasia, including mesotheloma, lymphoma, and extension of gastric squamous cell carcinoma
- Penetrating chest wounds
- Esophageal perforation
- Diaphragmatic hernia
- Congestive heart failure
- Hemangiosarcoma (causing hemotherax)
- African horse sickness
- Pulmonary hydatidosis\textsuperscript{29}
- Pulmonary infarction and pneumonia\textsuperscript{30}

**NECROPSY FINDINGS**

The pneumonia involves all areas of the lungs but is most severe in the cranial and ventral regions. The pleura are thickened and have adherent fibrin tags and there is excessive pleural fluid. The pleural fluid contains strands of fibrin and is usually cloudy and serosanguineous to yellow. Histologically, there is a purulent, fibrino­ necrotic pneumonia and pleuritis.

**TREATMENT**

Given early recognition of the disease and prompt institution of appropriate therapy the prognosis for horses with pleuropneumonia is favorable. However, the long course of the disease and the associated expense often limit therapeutic options and make the outcome a decision based on economic rather than medical grounds.

The principles of treatment are prompt, broad-spectrum antimicrobial therapy, removal of infected pleural fluid and cellular debris, including necrotic lung, relief of pain, correction of fluid and electrolyte abnormalities, relief of respiratory distress, treatment of complications, and prevention of laminitis.

**Antimicrobial treatment**

The prompt institution of systemic, broad-spectrum antimicrobial therapy is the single most important component of treatment of horses with pleuropneumonia. Antimicrobial therapy is almost always started before the results of bacterial culture of pleural fluid or tracheal aspirate are received and the antimicrobial sensitivity of isolated bacteria are determined. Use of antibiotics or combinations of antibiotics with a broad spectrum of antimicrobial activity is important.
because of the polymicrobial nature of most infections and because the wide range of Gram-positive and Gram-negative bacteria that may be associated with the disease makes prediction of the susceptibility of the causative organisms difficult. Furthermore, superinfection with bacteria, especially Enterobacteriaceae and obligate anaerobes, commonly occurs in horses with disease initially associated with a single bacterial species. Administration of drugs that are effective in the treatment of penicillin-resistant obligate anaerobes is also important.

**Recommended doses for antimicrobials** used in the treatment of pleuropneumonia are provided in Table 10.6. Antimicrobial therapy should be broad-spectrum to include coverage of the likely bacteria involved in the disease. It should therefore provide coverage against *Streptococcus* spp., *Actinobacillus/ Pasteurella* spp., Enterobacteriaceae and anaerobes, including *Bacteroides* spp. A combination of penicillin G, an aminoglycoside and metronidazole provides broad-spectrum coverage and is a frequently used empirical therapy until the results of bacterial culture are known. Results of bacterial culture and subsequent antimicrobial susceptibility testing may aid selection of further antimicrobials. However, superinfection with Gram-negative and anaerobic bacteria is common and there is a sound rationale for continued use of a combination of antimicrobials providing broad-spectrum coverage throughout treatment of the disease.

**Antimicrobial therapy will be prolonged** in most cases, usually being required for at least 1 month and often several months. As the disease resolves it may be possible to change from parenteral antibiotics to orally administered antibiotics such as a combination of trimethoprim–sulfonamide, although the clinical response to this combination is sometimes disappointing, doxycycline or enrofloxacin.

The decision to discontinue antimicrobial therapy should be based on lack of fever, nasal discharge, respiratory distress or cough, lack of evidence of intrathoracic abscesses on ultrasonographic and radiographic examination of the thorax, and resolution of neutrophilia and hyperfibrinogenemia. There should be no appreciable pleural fluid on ultrasonographic examination.

**Thoracic drainage**

Chronic, effective drainage of the pleural cavity and intrathoracic abscesses is critical for successful treatment of horses with pleuropneumonia. Horses with sterile pleural fluid may require only a single drainage of pleural fluid. More severely affected horses may require intermittent drainage on each of several days, and most cases will require insertion of a tube into the pleural space to provide continuous drainage for several days to several weeks. Horses with chronic disease may benefit from a thoracotomy that provides continuous drainage and the ability to lavage the chest. Ultrasonographic examination of the chest is very useful in identifying the presence of pleural fluid, the optimal sites for drainage and the efficacy of drainage.

**Intermittent thoracic drainage** can be achieved by inserting a bovine teat cannula or similar blunt cannula into the pleural space. This should be done aseptically and under local anesthesia. If ultrasonographic examination is not available, the cannula should be placed in the sixth to eighth intercostal space on the right side or the seventh to ninth on the left side just above the level of the diaphragm. Drainage is accomplished by manual aspiration or intercostal tubing, usually with a 22-44000 IU/kg IV 6 h

<table>
<thead>
<tr>
<th>Drug</th>
<th>Dose, route and interval</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Procaine penicillin G</td>
<td>22–44 000 IU/kg IM q 12 h</td>
<td>Effective against <em>Streptococcus</em> sp. and most anaerobes with the exception of <em>Bacteroides fragilis</em>. Achieves low plasma concentrations but has prolonged duration of action. Cheap. Synergistic with aminoglycosides. Should not be used as sole treatment.</td>
</tr>
<tr>
<td>Sodium or potassium penicillin G</td>
<td>22–44 000 IU/kg IV q 6 h</td>
<td>Effective against Gram-positive organisms (except penicillinase-producing bacteria such as <em>Staphylococcus</em> spp.) and most anaerobes. Achieves high plasma concentrations. Synergistic with aminoglycosides. Expensive.</td>
</tr>
<tr>
<td>Ampicillin sodium</td>
<td>11–22 mg/kg IV or IM q 6 h</td>
<td>Wider spectrum than penicillin G. Achieves high plasma concentrations. Synergistic with aminoglycosides. Expensive.</td>
</tr>
<tr>
<td>Ceftiofur sodium</td>
<td>2.2 mg/kg IM or IV q 12 h</td>
<td>Wider spectrum of action against Gram-positive and Gram-negative organisms and most anaerobes. Can be used as sole treatment, though not recommended. Clinical results sometimes disappointing.</td>
</tr>
<tr>
<td>Chloramphenicol</td>
<td>50 mg/kg, PO q 6 h</td>
<td>Good spectrum of action, including anaerobic bacteria. Poor oral bioavailability and disappointing clinical efficacy. Use prohibited in some countries. Potential human health hazard. Risk of diarrhea.</td>
</tr>
<tr>
<td>Gentamicin sulfate</td>
<td>7 mg/kg, IV or IM q 24 h</td>
<td>Active against <em>Staphylococcus</em> spp. and many Gram-negative organisms. Inactive against anaerobes. Poor activity against <em>Streptococcus</em> spp. Synergistic with penicillin.</td>
</tr>
<tr>
<td>Enrofloxacin</td>
<td>7 mg/kg IV or PO q 24 h</td>
<td>Active against some Gram-positive and Gram-negative bacteria. Not good or reliable activity against streptococci. Contraindicated in young animals because of risk of cartilage damage.</td>
</tr>
<tr>
<td>Amikacin sulfate</td>
<td>21 mg/kg IV or PO q 24 h</td>
<td>Theoretical wide spectrum of action. Disappointing clinical efficacy.</td>
</tr>
<tr>
<td>Trimethoprim–sulfonamides</td>
<td>15–30 mg/kg PO or IV q 24 h</td>
<td>Wider spectrum of action. Disappointing clinical efficacy.</td>
</tr>
<tr>
<td>Rifampin</td>
<td>5–10 mg/kg PO or IV q 12 h</td>
<td>Penetrates abscesses well. Active against Gram-positive and some Gram-negative bacteria. Must be used in conjunction with another antibiotic (not an aminoglycoside).</td>
</tr>
<tr>
<td>Doxycycline</td>
<td>10 mg/kg PO q 12 h</td>
<td>Broad spectrum of activity, but resistance unpredictable. Only moderate blood concentrations. Suitable for prolonged therapy but not treatment of the acute disease. Risk of diarrhea.</td>
</tr>
<tr>
<td>Ticarcillin–clavulanic acid</td>
<td>50 mg/kg IV q 6 h</td>
<td>Broader spectrum of Gram-negative activity than penicillin G. Expensive.</td>
</tr>
<tr>
<td>Metronidazole</td>
<td>15–25 mg/kg PO q 6–8 h</td>
<td>Active against anaerobes only. Used in conjunction with other antimicrobials (especially penicillin and aminoglycosides). Neurotoxicity rare.</td>

N, intravenously; PO, orally; IM = intramuscularly; q, dose administered every 'h' hours.
olecranon. Pleural fluid that does not contain large fibrin clots (which clog the cannula) can be drained and the cannula removed. However, the process is slow if large quantities of fluid must be removed. Intermittent drainage is indicated when the quantities of pleural fluid are small (< 5 L), relatively cell free or localized. This situation is most likely to occur in horses with acute disease.

**Insertion of large plastic chest tubes** (20–30 French, 6–10 mm outside diameter) facilitates rapid fluid removal, allows drainage of viscid fluid and provides continuous drainage. The chest tube should be inserted in an aseptic fashion under local anesthesia at sites indicated by ultrasonographic examination or as described above. A one-way valve should be attached to the external end of the tube to prevent aspiration of air and development of a pneumothorax. A balloon or condom with the end removed is an effective one-way valve. The chest tube is secured to the chest wall with a purse-string suture. The tube may be retained for several days to a week, but should be monitored frequently (every few hours) and cleared of fibrin clots as needed.

**Complications of drainage** of pleural fluid include: collapse of the animal if the fluid is removed too rapidly; pneumothorax; sudden death due to cardiac puncture or laceration of a coronary vessel; and perforation of abdominal viscera. Collapse can be prevented by administering fluids intravenously during pleural fluid drainage and by removing the fluid gradually (over a period of 30 min). Some horses develop a cellulitis around the chest tube that requires that the tube be removed.

**Thoracotomy** may be required in chronic cases to provide drainage of intrathoracic abscesses or chronic pleural effusion that is refractory to treatment with antibiotics. Thoracotomy is an effective intervention in many horses with advanced pleuropneumonia and should not be considered an emergency or heroic procedure.

**Pleural lavage** Infusion and subsequent removal of 5–10 L of warm saline or balance polyionic electrolyte solution into the affected pleural space may be beneficial in the treatment of cases with viscid fluid or fluid containing large amounts of fibrin and cell debris. The fluid can be infused through the chest tube that is used to drain the pleural space. Care should be taken not to introduce bacteria with the infusion.

**Supportive therapy** Acutely or severely ill horses may be dehydrated, azotemic, and have acid–base disturbance. These horses should be treated with appropriate fluids administered intravenously.

Pleuropneumonia is a painful disease and every attempt should be made to relieve the horse's chest pain. NSAIDs, including flunixin meglumine (1 mg/kg, orally, intramuscularly or intravenously, every 8 h) or phenylbutazone (2.2 mg/kg, orally or intravenously, every 12 h) often provide effective analgesia and presumably reduce inflammation in the pleural space.

Horses should be provided with good nursing care, including a comfortable stall, free access to palatable water, and a good diet. Affected horses will often not eat adequately and should be tempted with fresh and nutritious fodder.

Attention should be paid to the horse's feet to detect early signs of laminitis and allow appropriate measures to be taken.

**CONTROL** Prevention of pleuropneumonia involves reduction of risk factors associated with the disease. The main risk factors are other infectious respiratory disease and transportation. Every effort should be made to prevent and treat respiratory disease in athletic horses, including institution of effective vaccination programs. Horses with infectious respiratory disease should not be vigorously exercised until signs of disease have resolved.

Transportation of athletic horses is common and essential for their participation in competitive events. It cannot, therefore, be eliminated. Every effort should be made to minimize the adverse effects of transportation on airway health. Recommendations for transport of horses first made in 1917 are still relevant.\(^\text{32,33}\) Updated, these recommendations include:

- Not transporting a horse unless it is healthy. Horses with fever should not be transported
- Knowledgeable staff familiar with the horse should accompany it
- Suitable periods of rest and acclimation should be provided before recently transported or raced horses are transported
- The time during which horses are confined for transportation should be kept to a minimum. Horses should be loaded last and unloaded first in flights with mixed cargo
- The route taken should be the most direct and free of available Horses should be permitted adequate time to rest at scheduled breaks. If possible, on long journeys horses should be unloaded and allowed exercise (walking) and access to hay and water

Horses should have frequent, preferably continuous, access to feed and water during transportation.

- Horses should not be exercised after arrival until they are free of fever, cough, or nasal discharge
- Horses should not be restrained during transportation such that they are unable or unwilling to lower their heads
- Air quality should be optimal in the vehicle used to transport the horse.

Diseases of the upper respiratory tract

RHINITIS

Rhinitis (inflammation of the nasal mucosa) is characterized clinically by sneezing, wheezing, and stertor during inspiration and a nasal discharge that may be serous, mucoid, or purulent in consistency depending on the cause.

ETIOLOGY

Rhinitis usually occurs in conjunction with inflammation of other parts of the respiratory tract. It is present as a minor lesion in most bacterial and viral pneumonia but the diseases listed are those in which it occurs as an obvious and important part of the syndrome.

Cattle
- Catarhal rhinitis in infectious bovine rhinotracheitis, adenoviruses 1, 2 and 3 and respiratory syncytial virus infections
- Ulcerative/erosive rhinitis in bovine malignant catarrh, mucosal disease, rinderpest
- Rhinosporidiosis caused by fungi, the blood fluke Schistosoma nasalis and the supposedly allergic ‘summer snuffles’ also known as atopic rhinitis
- Familial allergic rhinitis in cattle in which the progeny of affected cows are susceptible to allergic rhinitis
- Bovine nasal eosinophilic granuloma due to Nocardia sp.

Horses
- Clandrugs, strangula, and epizootic lymphangitis
- Infections with the viruses of equine viral rhinopneumonitis (herpesvirus-1), equine viral arteritis, influenza H3N8 equine rhinovirus, parainfluenza virus, reovirus, adenovirus
- Chronic rhinitis claimed to be caused by dust in dusty stables, and acute rhinitis occurring after inhalation of smoke and fumes
- Nasal granulomas due to chronic infections with Pseudoallescheria boydii and Aspergillus, Conidiobolus and Mucoracaes fungi

Sheep and goats
- Melioidosis, bluetongue, rarely contagious erythema and sheep pox
- Oestrus ovis and Eleya ophora schneideri infestations
- Allergic rhinitis
- Purulent rhinitis and otitis associated with P aeruginosa in sheep showered with contaminated wash

Pigs
- Atrophic rhinitis, inclusion body rhinitis, swine influenza, some outbreaks of Aujeszky’s disease.

PATHOGENESIS

Rhinitis is of minor importance as a disease process except in severe cases when it causes obstruction of the passage of air through the nasal cavities. Its major importance is as an indication of the presence of some specific diseases. The type of lesion produced is important. The erosive and ulcerative lesions of rinderpest, bovine malignant catarrh and mucosal disease, the ulcerative lesions of glanders, melioidosis, and epizootic lymphangitis and the granular rhinitis of the anterior nares in allergic rhinitis all have diagnostic significance.

In atrophic rhinitis of pigs the destruction of the turbinate bones and distortion of the face appear to be a form of devitalization and atrophy of bone caused by a primary, inflammatory rhinitis. Secondary bacterial invasion of facial tissue of swine appears to be the basis of necrotic rhinitis.

CLINICAL FINDINGS

The primary clinical finding in rhinitis is a nasal discharge, which is usually serous initially but soon becomes mucoid and, in bacterial infections, purulent. Erythema, erosion, or ulceration may be visible on inspection. The inflammation may be unilateral or bilateral. Sneezing is characteristic in the early acute stages and this is followed in the later stages by snorting and the expulsion of large amounts of mucopurulent discharge. A chronic unilateral purulent nasal discharge lasting several weeks or months in horses suggests nasal granulomas associated with mycotic infections.

‘Summer snuffles’

‘Summer snuffles’ of cattle presents a characteristic syndrome involving several animals in a herd. Cases occur in the spring and autumn when the pasture is in flower and warm moist environmental conditions prevail. The disease may be most common in Channel Island breeds. There is a sudden onset of dyspnea with a profuse nasal discharge of thick, orange to yellow material that varies from a mucopurulent to caseous consistency. Sneezing, irritation, and obstruction are severe. The irritation may cause the animal to shake its head, rub its nose along the ground or poke its muzzle repeatedly into hedges and bushes. Sticks and twigs may be pushed up into the nostrils as a result and cause laceration and bleeding. Stertorous, difficult respiration accompanied by mouth breathing may be evident when both nostrils are obstructed. In the most severe cases a distinct pseudomembrane is formed that is later snorted out as a complete nasal cast. In the chronic stages multiple proliferative non-erosive nodules 2–8 mm in diameter and 4 mm high with marked mucosal edema are visible in the anterior nares.

Familial allergic rhinitis

In familial allergic rhinitis in cattle, the clinical signs begin in the spring and last until late fall. Affected animals exhibit episodes of violent sneezing and extreme pruritus manifested by rubbing their nostrils on the ground, trees, and other inanimate objects and frequently scratching the nares with their hind feet. Dyspnea and loud snoring sounds are common and affected animals frequently clean their nostrils with their tongues. The external nares contain a thick mucoid discharge and the nasal mucosa is edematous and hyperemic. The clinical abnormalities resolve during the winter months. All affected animals are positive to intradermal skin testing for a wide variety of allergens.

Mycotic rhinitis

Mycotic rhinitis in the horse is characterized by noisy respirations, circumferential narrowing of both nasal passages and thickening of the nasal septum. The nasal conchae and turbinates may be roughened and edematous, and the ventral meati decreased in size bilaterally. The nasal discharge may be unilateral or bilateral. Endoscopically, granulomas may be found in almost any location in the nasal cavities and extending on to the soft palate and into the maxillary sinus. The disease is discussed in detail in Chapter 24.

Endoscopic examination

Endoscopic examination using a flexible fiberoptic endoscope or a rigid endoscope is very useful for the visual inspection of lesions affecting the nasal mucosa of horses and cattle that are not visible externally. Radiographic or computed tomographic imaging can be used to detect atrophic rhinitis, although use of these techniques on a wide scale is clearly not practical.

CLINICAL PATHOLOGY

Examination of nasal swabs of scrapings for bacteria, inclusion bodies or fungi may aid in diagnosis. Discharges in allergic rhinitis usually contain many more eosinophils than normal. Nasal mucosal biopsy specimens are useful for microbiological and histopathological examination.
Rhinitis is not a fatal condition, although animals may die of specific diseases in which rhinitis is a prominent lesion.

**DIFFERENTIAL DIAGNOSIS**

Rhinitis is readily recognizable clinically. Differentiation of the specific diseases listed under Etiology, above, is discussed under their respective headings.

**Rhinosis in cattle** must be differentiated from maduromycosis, rhinosporidiosis, and infection with the pasture mite (Tyrophagus palmarum). The differential diagnosis may be difficult if allergic rhinitis occurs secondary to some of these infections.

**Rhinosis in the horse** must be differentiated from inflammation of the facial sinuses or guttural pouches in which the nasal discharge is usually purulent and persistent and often unilateral, and there is an absence of signs of nasal irritation. A malodorous nasal discharge, frontal bone distortion, draining tracts at the poll, and neurological abnormalities are common in cattle with chronic frontal sinusitis as a complication of dehorning.

**TREATMENT**

Specific treatment aimed at control of individual causative agents is described under each disease. Thick tenacious exudate that is causing nasal obstruction may be removed gently and the nasal cavities irrigated with saline. A nasal decongestant sprayed up into the nostrils may provide some relief. Newborn piglets with inclusion body rhinitis may be affected with severe inspiratory dyspnea and mouth-breathing that interferes with sucking. The removal of the exudate from each nostril followed by irrigation with a mixture of saline and antimicrobials will provide relief and minimize the development of a secondary bacterial rhinitis. Animals affected with allergic rhinitis should be taken off the pasture for about a week and treated with antihistamine preparations.

**OBSTRUCTION OF THE NASAL CAVITIES**

Nasal obstruction occurs commonly in cattle and sheep. The disease is usually chronic and due to:

- In sheep, infestation with *Oestrus ovis*
- In cattle, most often enzootic nasal granuloma, acute obstruction or the allergic condition ‘summer snuffles’. Cystic enlargement of the ventral nasal conchae in cattle can cause unilateral or bilateral nasal obstruction.

Minor occurrences include the following:

- Large mucus-filled polyps developing in the posterior nares of cattle and sheep and causing unilateral or bilateral obstruction
- Granulomatous lesions caused by a fungus, *Rhinosporidium* sp. and by the blood fluke, *Schistosoma nasalis*
- A chronic pyogranuloma due to *Coccidioides immitis* infection has occurred in the horse
- Foreign bodies may enter the cavities when cattle rub their muzzles in bushes in an attempt to relieve the irritation of acute allergic rhinitis
- Nasal amyloidosis occurs rarely in mature horses and is characterized clinically by stertorous breathing and raised, firm, nonpainful, nodular swellings on the rostral nasal septum and floor of the nasal cavity.
- Affected horses do not have any other illness and surgical removal of the lesions is recommended
- Infestation of the nasopharynx of horses by *Gasterophilus pectorum* causes obstruction of the upper airway.

**Neoplasms**

Neoplasms of the olfactory mucosa are not common but do occur, particularly in sheep, goats, and cattle, where the incidence in individual flocks and herds may be sufficiently high to suggest an infectious cause. The lesions are usually situated just in front of the ethmoid bone, are usually unilateral but may be bilateral and have the appearance of adenocarcinomas of moderate malignancy. In cattle, the disease is commonest in 6-9-year-olds and may be sufficiently extensive to cause bulging of the facial bones. The tumors are adenocarcinomas arising from the ethmoidal mucosa, and they metastasize in lungs and lymph nodes. Clinical signs include nasal discharge, often bloody, mouth-breathing and assumption of a stretched-neck posture. There is evidence to suggest that a virus may be associated. A similar syndrome is observed in cattle with other nasal tumors such as osteoma.

Neoplasia that obstructs the nasal cavity occurs in horses with squamous cell carcinoma or adenocarcinoma of the sinus or nasal cavity, angiosarcoma and a variety of other rare tumors. Epidermal inclusions cysts of the nasal diverticulum of horses can cause obstruction of the nasal cavity, but are not neoplasms. Cysts of the paranasal sinuses can cause marked facial deformity and obstruction to air passages.

**Enzootic nasal adenocarcinoma**

Enzootic nasal adenocarcinoma occurs in sheep and goats. The disease is sporadic but has occurred in related flocks, which suggests that it may be an enzootic problem. The clinical findings include a persistent serous, mucous, or mucopurulent nasal discharge and stridor. Affected sheep progressively develop anorexia, dyspnea, and mouth-breathing and most die within 90 days after the onset of signs. The tumors originate unilaterally or occasionally bilaterally in the olfactory mucosa of the ethmoid turbinates. They are locally invasive but not metastatic. Histologically the tumors are classified as adenomas or, more frequently, adenocarcinomas. The etiology is unknown, but a retrovirus may be involved. Budding and extracellular retrovirus-like particles have been observed ultrastructurally in enzootic nasal tumors of goats.

**Ethmoidal hematomas**

Ethmoidal hematomas are encapsulated, usually expanding, insidious, potentially distorting and obstructing lesions of the nasal cavities that occur in horses. Chronic unilateral nasal discharge is common and lesions are usually advanced at the time of diagnosis. There is stertorous breathing and upper airway obstruction in later stages of the disease. The nasal discharge is serous or mucoid and intermittently sanguineous, sanguinopurulent and usually unrelated to exercise. Diagnosis is made by endoscopy and radiography. Surgical removal is possible and successful in some cases. Multiple intralesional injection of formalin (1–100 mL of 10% neutral buffered formalin injected at 10 day intervals) through an endoscope can cure the tumor but there is the risk of serious adverse effects if the ethmoidal hematoma penetrates the cribriform plate. The procedure involves the injection of a sufficient volume of 10% neutral buffered formalin to distend the lesion. The formalin is injected via an endoscope once every 10 days until the lesion resolves by sloughing. Between one and 20 injections are required. However, the prognosis for long-term resolution of the tumor is poor because of high rates of recurrence.

**CLINICAL FINDINGS**

In cattle, sheep, and pigs there is severe inspiratory dyspnea when both cavities are blocked. The animals may show great distress and anxiety and breathe in gasps through the mouth. Obstruction is usually not complete and a loud, wheezing sound occurs with each inspiration. A nasal discharge is usually present but varies from a small amount of blood-stained serous discharge when there is a foreign body present to large quantities of purulent exudate in allergic rhinitis. Shaking of the head and snorting are also common signs. If the obstruction is unilateral the distress is not so marked and the difference in breath streams...
ETIOLOGY
Epistaxis occurs commonly in the horse and may be due to lesions in the nasal cavity, nasopharynx, auditory tube diverticulum (guttural pouch) or lungs (see Table 10.5). Exercise-induced pulmonary hemorrhage is described under that heading earlier in this chapter.

Hemorrhagic lesions of the nasal cavity, nasopharynx, and guttural pouch in the horse usually cause unilateral epistaxis of varying degree depending on the severity of the lesions. Pulmonary lesions in the horse resulting in hemorrhage into the lumen of the bronchi also result in epistaxis. Blood originating from the lungs of the horse is discharged most commonly from the nostrils and not the mouth because of the horse's long soft palate. Also, blood from the lungs of the horse is not foamy when seen at the nose because the horizontal position of the major bronchi allows blood to flow out freely without being coughed up and made foamy. It was previously thought that upper respiratory tract hemorrhage could be distinguished from lower respiratory tract hemorrhage by the blood in the latter case being foamy. This does not apply in the horse. Froth is usually the result of pulmonary edema, in which case it is a very fine, pink, stable froth.

Bleeding from lesions of the upper respiratory tract of horses usually occur spontaneously while the horse is at rest. One of the commonest causes of unilateral epistaxis in the horse is mycotic ulceration of the blood vessels in the wall of the guttural pouch (guttural pouch mycosis).

Other less common causes of nasal bleeding include hemorrhagic polyps of the mucosa of the nasal cavity or paranasal sinuses, and encapsulated hematomas, which look like hemorrhagic polyps, commencing near the ethmoidal labyrinth and expanding into the nasal cavity and the pharynx. There is respiratory obstruction, coughing, choking, and persistent unilateral epistaxis. The capsule of the hematoma is respiratory epithelium. Surgical correction has been achieved. Another cause, most uncommonly, is a parasitic arteritis of the internal carotid artery as it courses around the guttural pouch.1

Mild epistaxis is a common finding in horses and cattle with severe thrombocytopenia.2 Erosions of the nasal mucosa in glanders, granulomatous and neoplastic diseases and trauma due to passage of a nasal tube or endoscope, or from physical trauma externally, are other obvious causes.

A case of fibrous dysplasia in the ventral meatus of a horse with epistaxis is recorded.3 Similarly, in congestive heart failure and purpura hemorrhagica there may be a mild epistaxis.

Neoplasia, and notably hemangiosarcoma, of the upper or lower respiratory tract can cause epistaxis.4 Envenomation of horses by rattlesnakes in the western USA caused a clinical syndrome that includes swelling of the head, dyspnea, and epistaxis.5 Poisoning by bracken fern or moldy sweet clover is a common cause of spontaneous epistaxis in cattle. The epistaxis may be bilateral, and hemorrhages of other visible and subcutaneous mucous membranes are common. An enzootic ethmoidal tumor has been described in cattle in Brazil and was at one time a disease of some importance in Sweden.6 The lesion occupies the nasal cavities, causes epistaxis and may invade paranasal sinuses.

In hemoptysis in horses the blood flows along the trachea and pooling in the larynx until the swallowing reflex is stimulated and swallowing occurs; or coughing is stimulated and blood is expelled through the mouth and nostrils. In some horses repeated swallowing, without eating or drinking, can be a good indicator that bleeding is occurring. The origin of the hemorrhage is usually in the lungs and in cattle the usual cause is pneumonia.5 Pulmonary hemorrhage is usually originating from a hepatic abscess,7 or the hemorrhages may be caused by disease of the lungs,7 as a result of pulmonary edema, in which case it is a very fine, pink, stable froth.

The origin of the hemorrhage in epistaxis and hemoptysis may be obvious, as in passage of injury to the turbinates during passage of a stomach tube intranasally or if a systemic disease with bleeding defects is present. In many other cases, however, the origin of the hemorrhage is not obvious and special examination procedures may be required. Careful auscultation of the lungs for evidence of abnormal lung sounds associated with pulmonary diseases is necessary.

CLINICAL EXAMINATION
The nasal cavities should be examined visually with the aid of a strong, pointed source of light through the external nares. Only the first part of the nasal cavity can be examined directly but an assessment of the integrity of the nasal mucosa can usually be made. In epistaxis due to systemic disease or clotting defects the blood on the nasal mucosa will usually not be clotted. When there has been recent traumatic injury to the nasal...
mucosa or erosion of a blood vessel by a space-occupying lesion such as tumor or nasal polyp, the blood will usually be found in clots in the external nares.

The nasal cavities should then be examined for any evidence of obstruction as set out in the previous section. When the blood originates from a pharyngeal lesion there are frequent swallowing movements and a short explosive cough, which may be accompanied by the expulsion of blood from the mouth. Hematological examinations are indicated to assist in the diagnosis of systemic disease or clotting defects. Radiological examinations of the head are indicated when space-occupying lesions are suspected.

In the horse, the use of the flexible fiberoptic endoscope will permit a thorough examination of the nasal cavities, nasopharynx, guttural pouch and larynx, trachea and major bronchi.

**TREATMENT**
Specific treatment of epistaxis and hemoptysis depends on the cause. Hemorrhage from traumatic injuries to the nasal mucosa does not usually require any treatment. Space-occupying lesions of the nasal mucosa may warrant surgical therapy. Epistaxis associated with guttural pouch mycosis may require mycotic abortion of the affected artery. The ineffectiveness of therapy for exercise-induced pulmonary hemorrhage has been discussed above. There is no successful treatment for the hemoptysis due to pulmonary aneurysm and posterior venal thrombosis in cattle. General supportive therapy is as for any spontaneous hemorrhage and includes rest, blood transfusions, and hematins.

**REFERENCES**

**LARYNGITIS, TRACHEITIS, BRONCHITIS**

Inflammation of the air passages usually involves all levels and no attempt is made here to differentiate between inflammations of various parts of the tract. They are all characterized by cough, noisy inspiration and some degree of inspiratory embarrassment.

**ETIOLOGY**
All infections of the upper respiratory tract cause inflammation, either acutely or as chronic diseases. In most diseases the laryngitis, tracheitis, and bronchitis form only a part of the syndrome and the causes listed below are those diseases in which upper respiratory infection is a prominent feature.

**Cattle**
- Infectious bovine rhinotracheitis (bovine herpesvirus-1), calf diphtheria (necrotic laryngitis), *Histophilus somnus*
- Tracheal stenosis in feedlot cattle, 'honker cattle', etiology unknown
- Congenital cavitation of the arytenoid may contribute to laryngeal abscess development
- *Syngamus senyugas* infests the larynx of cattle in the tropics.

**Sheep**
- Chronic infection with *Actinomyces pyogenes*.

**Horses**
- Equine herpesvirus (EVR), equine viral arteritis (EVA), equine viral influenza (EVI), strangles (*S. equi*),* Idiopathic ulceration of the mucosa covering the arytenoid cartilages*.

**Pigs**
- Swine influenza.

**PATHOGENESIS**

Irritation of the mucosa causes frequent coughing, and swelling causes partial obstruction of the air passages, with resulting inspiratory dyspnea. Necrotic laryngitis in calves is associated with marked changes in pulmonary function, modifies tracheal dynamics and disturbs the growth process by increasing the energetic cost of breathing; this can result in impaired feed intake and predisposition to secondary pulmonary infection and subsequent respiratory failure from progressive exhaustion.

**CLINICAL FINDINGS**

Coughing and inspiratory dyspnea with laryngeal roaring or stridor are the common clinical signs. In the early stages of acute infections the cough is usually dry and nonproductive and is easily induced by grasping the trachea or larynx, or by exposure to cold air or dusty atmospheres. In acute laryngitis, the soft tissues around the larynx are usually enlarged and painful on palpation. In chronic affections, the cough may be less frequent and distressing and is usually dry and harsh. If the lesions cause much exudation or ulceration of the mucosa, as in bacterial tracheobronchitis secondary to infectious bovine rhinotracheitis in cattle, the cough is moist, and thick mucus, flecks of blood and fibrin may be coughed up. The cough is very painful and the animal makes attempts to suppress it.

Fever and toxemia are common and affected animals cannot eat or drink normally.

Inspiratory dyspnea varies with the degree of obstruction and is usually accompanied by a loud stridor and harsh breath sounds on each inspiration. These are best heard over the trachea although they are quite audible over the base of the lung, being most distinct on inspiration. The respiratory movements are usually deeper than normal and the inspiratory phase more prolonged and forceful. Additional signs, indicative of the presence of a primary specific disease, may also be present.

**Examination of the larynx** is usually possible through the oral cavity using a cylindrical speculum of appropriate size and a bright, pointed source of light. This is done relatively easily in cattle, sheep, and pigs but is difficult in the horse. Lesions of the mucosa of the arytenoid cartilages and the vault of the larynx are usually visible if care and time are taken. In laryngitis, there is usually an excessive quantity of mucus, which may contain flecks of blood or pus in the pharynx. Palpation of the pharyngeal and laryngeal areas may reveal lesions not readily visible through a speculum. During opening of the larynx, lesions in the upper part of the trachea are sometimes visible. The use of a fiberoptic endoscope allows a detailed examination of the upper respiratory tract.

Inflammation or lesions of the larynx may be severe enough to cause marked inspiratory dyspnea and death from asphyxia. In calves and young cattle with diphtheria the lesion may be large enough (or have a pedicle and act like a valve) to cause severe inspiratory dyspnea, cyanosis, anxiety and rapid death. The excitement associated with loading for transportation to a clinic or of a clinical examination, particularly the oral examination of the larynx, can exaggerate the dyspnea and necessitate an emergency tracheotomy.

Most cases of bacterial laryngitis will heal without obvious residual sign after several days of antimicrobial therapy. Some cases in cattle become chronic in spite of therapy due to the inflammation extending down into the arytenoid cartilages resulting in a chronic chondritis due to a sequestrum similar to osteomyelitis. Abscess formation is another common cause of chronicity. Secondary bacterial infection of primary viral diseases, or extension of bacterial infections to the lungs commonly results in pneumonia.

**Tracheal stenosis** in cattle is characterized by extensive edema and hemorrhage of the dorsal wall of the trachea, resulting in coughing (honking), dyspnea...
Upper respiratory infections are not laryngeal edema associated with some.

**TREATMENT**

Laboratory examinations may be of value in determining the presence of specific diseases.

**Necropsy Findings**

Upper respiratory infections are not usually fatal but lesions vary from acute catarrhal inflammation to chronic granulomatous lesions depending upon the duration and severity of the infection. When secondary bacterial invasion occurs accumulation of exudate and necrotic tissue at the tracheal bifurcation and in the dependent bronchi.

**DIFFERENTIAL DIAGNOSIS**

Inflammation of the larynx usually results in coughing, and inspiratory dyspnea with a stertor and loud abnormal laryngeal sounds on auscultation over the trachea and over the base of the lungs on inspiration. Lesions of the larynx are usually visible by laryngoscopic examination, those of the trachea and major bronchi are not so obvious unless special endoscopic procedures are used. Every reasonable effort should be used to inspect the larynx and trachea. Obstruction of the nasal cavities and other parts of the upper respiratory tract may also be difficult to distinguish unless other signs are present.

**TREATMENT**

Most of the common viral infections of larynx, trachea, and major bronchi will resolve spontaneously if the affected animals are rested, not worked and not exposed to inclement weather and dusty feeds. Secondary bacterial complications must be recognized and treated with the appropriate antimicrobial.

The bacterial infections can result in severe inflammation with necrosis and granulomatous lesions and must be treated with antimicrobials. Calves with calf diphtheria should be treated with a broad-spectrum antimicrobial daily or broad-spectrum antimicrobial daily or more often for up to 3 weeks or more may be necessary for treatment of the chondritis.

NSAIDs such as flunixin meglumide may be used in an attempt to reduce the laryngeal edema associated with some severe cases of bacterial laryngitis in cattle.

Animals with severe lesions and marked inspiratory dyspnea may require a tracheotomy and insertion of a tracheotomy tube for several days until the lesion heals. The tube must be removed, cleaned out and replaced at least once daily because of the accumulation of dried mucus plugs which interfere with respiration. The techniques of tracheotomy and permanent tracheostomy in the horse have been described.

Surgical excision of chronic granulomatous lesions and abscesses of the larynx may be indicated following failure of long-term antimicrobial therapy but postoperative complications of laryngeal and pharyngeal paralyses may occur.

Laryngotomy as a treatment for chronic laryngeal obstruction in cattle with long-term survival of 58% has been described.

**Tracheal Laryngotomy**

Calves with chronic laryngeal obstruction due to necrobacillosis has been used with a high degree of success. Under general anesthesia and dorsal recumbency, an incision is made over the lower third of the thyroid and cricoid cartilages and the first two tracheal rings. The larynx is easily visualized and necrotic tissue removed using a curette. The edges of the cartilages are sutured closed. A wedge-shaped piece of the first two tracheal rings is removed to create a tracheostomy, which is allowed to close after about 1 week when the postoperative swelling has subsided with the aid of daily care of the surgical site and the possible use of flunixin meglumide. No tracheotomy tube is required.

**REFERENCES**

**TRAUMATIC LARYNGOTRACHEITIS, TRACHEAL COMPRESSION AND TRACHEAL COLLAPSE**

Trumatic laryngotracheal injury can occur following endotracheal intubation used for general anesthesia. Nasotracheal intubation can result in mucosal injury to the nasal meatus, the arytenoid cartilages, the trachea, the dorsal pharyngeal recess, the vocal cords and the entrance to the guttural pouches. The laryngeal injury is attributed to the tube pressure on the arytenoid cartilages and vocal folds and the tracheal damage is due to the pressure exerted by the inflated cuff on the tracheal mucosa.

**Tracheal Collapse**

Tracheal collapse occurs in calves, in mature cattle, in goats and in horses, including miniature horses and foals.

Dynamic collapse is a cause of exercise intolerance in race horses that is evident only by endoscopic examination of the trachea during strenuous exercise.

Restriction of the tracheal lumen and laxity of the dorsal tracheal membrane results in varying degrees of inspiratory dyspnea with stridor, coughing, and reduced exercise tolerance. A ‘honing’ respiratory noise is common in affected calves when coughing spontaneously or when the trachea is palpated. Tracheal collapse in calves is associated with injuries associated with dystocia and clinical signs usually occur within a few weeks after birth. In some cases the trachea is compressed at the level of the thoracic inlet in association with callus formation of healing fractured ribs attributed to dystocia. In some cases in cattle, there is no history of dystocia or previous disease or previous manipulation of the trachea and the overall lumen size may be reduced to less than 25% of normal. Auscultation of the trachea may reveal loud referred upper airway sounds. Tracheal prostheses have been used for the treatment of tracheal collapse in calves and miniature horses.

**Tracheal Obstruction**

Can result from tracheitis associated with pneumonia in the horse, tracheal neoplasia, tracheal stenosis, presence of foreign bodies in the trachea and confinement by masses external to the trachea. It is suggested that increased respiratory effort associated with pneumonia causes collapse of the soft tissue structures of the trachea, rather than collapse of the tracheal rings. Tracheal rupture due to blunt trauma in the horse may result in severe subcutaneous emphysema and mediastinal emphysema. Conservative therapy is usually successful. Tracheal compression secondary to enlargement of the cranial mediastinal lymph nodes can also cause inspiratory dyspnea.

**REFERENCES**

**Pharyngitis**

Pharyngitis in all species is associated with infectious diseases of the upper.
airway. It is most studied in horses, probably because of the frequency of examination of the upper airway in this species. Pharyngitis in horses has many similarities to tonsillitis in children. The disorder in horses involves follicular lymphoid hyperplasia of the pharynx and involves both the pharyngeal tonsil and the extensive and diffuse lymphoid tissue in the walls and dorsal aspect of the pharynx. These tissues form the mucosal associated lymphoid tissues and are an important component of the normal immunological response of horses. The condition occurs in approximately 34% of Thoroughbred race horses and is probably as common in other breeds of horse. The condition is first detectable in 2-3-month-old foals and reaches its highest prevalence and greatest severity in yearlings and 2-year-old horses in race training. It is evident on endoscopic examination as diffuse, multiple, small, white nodules in the roof and walls of the pharynx. The nodules can be confluent and there is often excessive mucus present in severely affected horses. The clinical significance of the condition is debated. Affected race horses do not have impaired race performance. Affected horses recover spontaneously as they age, or after treatment with topical anti-inflammatory drugs. The condition is probably a normal aging process and necessary for development of a competent immune system in young horses.

Infestation of the nasopharynx of horses by larvae of the bot fly Gasterophilus pecorum causes obstruction of the upper airway and a parasitic pharyngitis. Diagnosis is by visualization of the parasite during endoscopic examination.

UPPER AIRWAY OBSTRUCTION IN HORSES: LARYNGEAL HEMIPLEGIA ('ROARERS')

Obstruction of the upper airway is a common cause of exercise intolerance in horses and is characterized in most cases by unusual respiratory noise during heavy exercise.

ETIOLOGY
The cause of laryngeal hemiplegia is degeneration of the recurrent laryngeal nerve with subsequent neurogenic atrophy of the cricoarytenoid dorsals and other intrinsic muscles of the larynx. The etiology of neuronal degeneration is unknown but the pathological changes are typical of a distal axonopathy. The disease is usually idiopathic but occasional cases are caused by guttural pouch mycosis or inadvertent perivascular injection of irritant material, such as phenylbutazone, around the jugular vein and vagosympathetic trunk. Bilateral laryngeal paralysis is usually associated with intoxication (organophosphate, haloxon) or trauma from endotracheal intubation during general anesthesia.

EPIDEMIOLOGY
Prevalence
The disease affects large horses more commonly than ponies, and it is commonly recognized in draft horses, Thoroughbreds, Standardbreds, Warmbloods and other breeds of large horse. The prevalence of laryngeal hemiplegia in Thoroughbred horses in training is between 1.8 and 13% depending, among other factors, on the criteria used to diagnose the condition. Among apparently normal Thoroughbred horses examined after racing, grade 4 laryngeal hemiplegia was detected in 0.3% of 744 horses, grade 3 in 0.1%, and grade 2 in 1.1%. Male horses over 160 cm tall are at most risk of developing the disease. There is evidence of a familial distribution of the disease with offspring of affected parents being more frequently affected (61%) than adult offspring of unaffected parents (40%).

PATHOGENESIS
Axonal degeneration causes preferential atrophy of the adductor muscles of the larynx, although both adductor (dorsal cricoarytenoid muscle) and adductor (lateral cricoarytenoid muscle) are involved. Fiber-type grouping of laryngeal muscles, evidence of recurrent laryngeal neuropathy, is present in draft foals as young as 2 weeks of age, indicating an early onset of the disease. The disease is progressive in some horses.

Compromised function of the adductor muscles results in partial occlusion of the larynx by the arytenoid cartilage and vocal fold during inspiration. The obstruction is most severe when airflow rates through the larynx are large, such as during strenuous exercise. Laryngeal obstruction increases the work of breathing, decreases the maximal rate of oxygen consumption and exacerbates the hypoxemia and hypercarbia normally associated with strenuous exercise by horses. These effects result in a severe limitation to athletic capacity and performance.

CLINICAL FINDINGS
Clinical findings include exercise intolerance and production of a whistling or roaring noise during strenuous exercise.

The disease can be detected by analysis of respiratory noise. Endoscopic examination of the upper airway provides the definitive diagnosis in most cases. Examination of the larynx is performed with the horse at rest and the position and movement of the arytenoid cartilages assessed. Laryngeal function can also be observed during swallowing, brief (30-60 s) bilateral nasal occlusion, and during and after exercise. Endoscopic examination during strenuous exercise on a treadmill of horses with grade III disease may be beneficial in determining the severity of the disease. Horses with early or mild degeneration of the recurrent laryngeal nerve and associated laryngeal musculature can have normal laryngeal function at rest. However, the loss of muscle function becomes apparent during exercise, when the laryngeal muscles of affected animals fatigue more rapidly than do those of normal animals, with the result that laryngeal dysfunction can become apparent during or immediately after exercise. Endoscopic examination during exercise is useful in differentiating the disease from axial deviation of the aryepiglottic folds.

The severity of the disease is graded I through IV:

- Grade I is normal, there being synchronous, full abduction and adduction of both arytenoid cartilages
- Grade II presents as weakness of the adductors evident as asynchronous movement and fluttering of the arytenoid cartilage during inspiration and expiration, but with full abduction during swallowing or nasal occlusion
- Grade III has asynchronous movement of the arytenoid cartilage during inspiration or expiration; full abduction is not achieved during swallowing or nasal occlusion
- Grade IV implies marked asymmetry of the larynx at rest and no substantial movement of the arytenoid cartilage during respiration swallowing or nasal occlusion

There are no characteristic changes in the hemogram or in serum biochemical variables in resting horses. During exercise there is a marked exacerbation of the normal exercise-induced hypoxemia and the development of hypercapnia in affected horses.

Necropsy Findings
Lesions are confined to an axonopathy of the recurrent laryngeal nerves and neurogenic muscle atrophy of the intrinsic muscles of the larynx.

Diagnostic Confirmation
Diagnostic confirmation is achieved by endoscopic examination of the larynx.
Differential diagnosis

Differential diagnoses of exercise intolerance and exercise-induced respiratory noise include:

- Dorsal displacement of the soft palate
- Subepiglottic cysts
- Arytenoid chondritis
- Arypepiglottic fold entrapment
- Axial deviation of the arypepiglottic folds

**TREATMENT**

Treatment requires a prosthetic laryngoplasty with or without ventriculoplasty. The disease is not life-threatening and strenuous or in which respiratory noise bothersome to the rider may not require surgery.

**REFERENCES**

**DORSAL DISPLACEMENT OF THE SOFT PALATE (SOFT PALATE PARESIS)**

The soft palate of equids is unique in that it provides an airtight seal between the oropharynx and nasopharynx during respiration. The horse is an obligate nasal breather except during very unusual circumstances. During swallowing the soft palate is transiently displaced dorsally as part of the normal act of deglutition to permit passage of the food bolus. Displacement of the soft palate other than during deglutition is abnormal and can be intermittent, which is usually associated with exercise, or persistent, which is usually associated with disruption of the nerve supply to the pharynx.

**INTERMITTENT DORSAL DISPLACEMENT OF THE SOFT PALATE**

Intermittent dorsal displacement of the soft palate occurs during exercise in some horses and causes an inspiratory obstruction to air flow through the larynx and pharynx. Estimates of the prevalence of the disease are unreliable because of the transient nature of the displacement and the fact that it only occurs during exercise. It is estimated to occur in 0.5–1.3% of Thoroughbred racehorses. The cause of intermittent displacement of the soft palate during exercise is unknown, although a number of mechanisms, including palatal myositis, ulcers of the caudal border of the soft palate, caudal retraction of the larynx and lower respiratory disease, are suggested. Retropharyngeal lymphadenopathy can cause neurogenic paresis of the pharyngeal and palatal muscles, with dorsal displacement of the soft palate the most obvious sign of pharyngeal collapse during exercise. The immediate cause of the displacement is the negative intrapharyngeal pressure generated during exercise.

Displacement of the soft palate during strenuous exercise places the soft palate dorsal to the epiglottis, a position in which it impedes flow of air during expiration. Peak expiratory airflow, minute ventilation, tidal volume and rate of oxygen consumption are all decreased in horses with dorsal displacement of the soft palate, whereas inspiratory flow and breathing rate are not affected.

**Clinical signs**

The clinical signs include exercise intolerance and intermittent production of a gurgling noise during strenuous exercise.

**Endoscopic examination**

Endoscopic examination of resting horses usually demonstrates a normal pharynx and larynx. Brief nasal occlusion (30–60s) that induces displacement of the soft palate, in combination with a history of respiratory noise during exercise, increases the likelihood of the disorder. Endoscopic examination of affected horses during exercise or immediately after may reveal dorsal displacement of the soft palate. Radiographic examination of the pharynx may reveal a shortened epiglottis (< 7 cm) in some affected horses.

**Differential diagnosis**

Differential diagnoses for exercise intolerance and respiratory noise include laryngeal hemiplegia, subepiglottic cysts, arytenoid chondritis and arypepiglottic fold entrapment. The important differentiating factor is that the noise occurs predominantly during expiration, and has a more gurgling sound to it than does the noise produced by horses with laryngeal hemiplegia.

**Treatment**

There is no definitive treatment. Usual methods of surgical intervention include augmentation of the epiglottis by injection of polytetrafluoroethylene (Teflon) paste, resection of the caudal edge of the soft palate or sternothyrohyoid muscle myectomy, although some of these interventions may have deleterious effects on upper airway airflow. A newer surgical technique involves the ‘laryngeal tie-forward’ procedure. Reports of success of surgical treatment of the disease are not definitive, in part because horses with the disorder that went untreated are not examined. It is plausible that the response to surgical treatment could be the result of enforced rest rather than the manipulation. Treatment of retropharyngeal lymphadenopathy may be beneficial. Nonsurgical treatment includes the use of anti-inflammatory drugs, tongue-ties, a variety of bits and a laryngohyoid support apparatus.

**Persistent dorsal displacement of the soft palate**

Persistent dorsal displacement of the soft palate is usually the result of damage to the innervation of the pharyngeal and palatal muscles as a result of:

- Guttural pouch mycosis
- Guttural pouch empyma
- Retropharyngeal lymph node abscission
- Equine protozoal myeloencephalitis
- Otitis media
- Myositis or muscle disease, such as white muscle disease
- Botulism.

Blockade of the pharyngeal branch of the vagus nerve by injection of local anesthetic causes persistent dorsal displacement of the soft palate whereas blockade of the hypoglossal and glossopharyngeal nerves does not.

**Clinical signs**

Persistent dorsal displacement of the soft palate causes dysphagia and stertorous respiration. Food material discharges from the nares and there is frequent coughing, probably secondary to the aspiration of feed material. Affected horses may develop aspiration pneumonia. If the condition persists, there is dehydration and weight loss. Endoscopic examination of the upper airways reveals dorsal displacement of the soft palate and may reveal other abnormalities, such as guttural pouch mycosis, that may provide a cause for the disease.

**Treatment**

Treatment should be directed toward resolution of the underlying disease, and provision of food and water. It is often
necessary to feed affected horses through a nasogastric tube.

REFERENCES

OTHER CONDITIONS OF THE UPPER AIRWAY OF HORSES

Aryepiglottic fold entrapment (epiglottic entrapment)
Entrapment of the epiglottis in the fold of tissue that extends from the arytenoid cartilage to the ventrolateral aspect of the epiglottis causes exercise intolerance and respiratory noise during exercise in racehorses. The disorder occurs in both young and mature race horses, and is found in approximately 1% of Thoroughbred race horses. The entrapment is often detected during rhinolaryngoscopic examination of racehorses, although it might not be the cause of poor performance. The presence of aryepiglottic fold entrapment causes a predominantly expiratory obstruction to airflow across the larynx during exercise. The interference with airflow, if any, does not appreciably impair performance in all horses.

Clinical signs
Clinical signs are of exercise intolerance and respiratory noise during exercise. Acute cases can be associated with epiglottitis, whereas chronic cases are usually an incidental finding during endoscopic examination of the upper airway.

Endoscopic examination of the upper airway reveals the border of the epiglottis to be obscured by the aryepiglottic folds. Normally, the serrated margin of the epiglottis and dorsal blood vessels extending to the lateral margins of the epiglottis are readily apparent, but when the epiglottis is entrapped these features are no longer visible. Because of the frequently intermittent nature of the entrapment, the horse should be examined on several occasions and preferably immediately after strenuous exercise. Radiography of the pharynx reveals the entrapped epiglottis.

Treatment
Treatment consists of surgical revision of the aryepiglottic fold. However, given that the chronic condition has not been demonstrated to adversely affect performance, and that the complication rate for surgical correction of the disorder is 60%, careful consideration should be given to not attempting surgical repair, especially in animals performing to expectations. Entrapment associated with acute epiglottitis should include administration of antimicrobials and anti-inflammatory agents to resolve the epiglottitis.

Epiglottitis
This is usually a disease of racehorses, although animals of any age can be affected. The clinical signs are exercise intolerance, respiratory noise and coughing. The disease can readily be mistaken for epiglottic entrapment. The epiglottis is thickened and ulcerated, and these changes are apparent on endoscopic examination. Treatment includes topical application of a mixture of nitrofurazone, dimethyl sulfoxide, glycerin and prednisolone, and systemic administration of anti-inflammatory drugs. The prognosis for recovery is excellent.

Subepiglottic cysts
Fluid-filled cysts in the subepiglottic, dorsal pharyngeal or soft palate tissues cause exercise intolerance and abnormal respiratory noise in exercising adult horses and mild dysphagia, chronic cough and nasal discharge in foals. The cysts are usually embryonic remnants, although cysts may be acquired in adult horses by obstruction or inflammation of mucous glands. Endoscopic examination of the upper airway reveals the presence of smooth-walled cysts. Subepiglottic cysts may only be apparent on careful examination of the epiglottis, although most will cause the epiglottis to assume a more upright posture than is normal. Treatment is surgical removal.

Arytenoid chondritis
This is a progressive disease of the arytenoid cartilages in which there is distortion of the cartilage with consequent partial occlusion of the lumen of the larynx. The cause of the disease is not known but it is most common in racehorses in heavy work. Distortion and swelling of the cartilage, combined with restricted abduction, increase resistance to airflow through the larynx and cause respiratory noise during exercise and exercise intolerance. In severe cases respiratory noise and increased respiratory effort may be apparent at rest. The disease can occur as a progression of idiopathic mucosal ulceration of the axial aspect of the arytenoid cartilages.

Endoscopic examination reveals the cartilage to be enlarged and distorted and there may be luminal projections of cartilage and granulation tissue. In less severe cases there is mild swelling of the cartilage and ulceration of the mucosa covering the cartilage. Bilateral disease is uncommon. The cartilage contains areas of necrosis, dystrophic mineralization and granulation tissue.

Treatment
Treatment requires surgical removal of the affected cartilage, although progression of the disease can be achieved in horses with mild lesions by administration of antimicrobials and anti-inflammatory drugs.

Mucosal lesions of the arytenoid cartilages
Lesions of the mucosa of the axial aspect of the arytenoid cartilages are observed in Thoroughbred race horses. The condition occurs in approximately 2.5% of Thoroughbred race horses and 0.6% of Thoroughbred yearlings. The pathogenesis is unknown. The disorder is recognized during endoscopic examination of the horses for other reasons (before sale, examination for exercise-induced pulmonary hemorrhage). Endoscopic appearance of the lesion is that of a roughly circular lesion of the mucosa of the axial surface of the arytenoid cartilage, with or without visible evidence of inflammation, and without deformity of the underlying cartilage. The lesions can progress to arytenoid chondritis, although most do not. Because of the risk of progression, medical therapy including systemic or local administration of antimicrobial and anti-inflammatory drugs is indicated. The prognosis for full recovery is excellent.

Axial deviation of the aryepiglottic folds
This is one of the most common abnormalities detected during laryngoscopic examination of horses running on a treadmill. The disorder can only be detected in horses by endoscopic examination of the larynx while the horse is performing strenuous exercise. Collapse of the axial portion of the aryepiglottic folds causes obstruction of the laryngeal airway during inspiration. Treatment is by transendoscopic laser ablation of the portion of the fold that collapses during exercise.

Epiglottic retroversion
This uncommon cause of exercise intolerance and respiratory noise during strenuous exercise is detected during endoscopic examination of exercising horses. During exercise, the epiglottis of affected horses flips into the larynx during inspiration and back to its normal position during expiration. The cause is unknown but the condition can be
induced by injection of local anesthetic around the hypoglossal and glossopharyngeal nerves. Treatment is rest.

**Retropharyngeal lymphadenopathy**
Lymphadenopathy of the retropharyngeal lymph nodes is usually associated with *S. equi* var. *equi* infection and is often a sequel to strangles (see Strangles). Shredding of *S. equi* from clinically inapparent retropharyngeal lymph node abscesses is an important source of new infections in horse barns. Retropharyngeal lymphadenopathy is also caused by trauma to the pharynx and neoplasia (predominantly lymphosarcoma). Enlargement of the retropharyngeal lymph nodes compresses the nasopharynx, increases resistance to airflow and may impair swallowing.

**Clinical signs**
Clinical signs are swelling of the parotid region, although this may be slight even in horses with marked respiratory distress, pain on palpation of the parotid region, stertorous respiratory noise, respiratory distress and dysphagia evident in horses with marked respiratory distress may require a tracheotomy. Horses that have severe respiratory distress will require assisted ventilation.

**Empyema**
The bacterial disease is usually caused by *S. equi* var. *equi* infection and is a recognized sequel to strangles. Empyema may be associated with other conditions of the guttural pouches, especially if there is impaired drainage of the pouch through the pharyngeal opening of the eustachian tube.

**DISEASES OF THE GUTTURAL POUCHES (AUDITORY TUBE DIVERTICULUM, EUSTACHIAN TUBE DIVERTICULUM)**

The guttural pouches are diverticula of the auditory (or eustachian) tubes found in equids and a limited number of other species. The function of the guttural pouch is unclear, although it may have a role in regulation of cerebral blood pressure, swallowing, and hearing. It is unlikely to have a role in brain cooling.

**GUTTURAL POUCH EMPYEMA**

**ETIOLOGY**
Empyema is the accumulation of purulent material in one or both guttural pouches. Initially, the purulent material is liquid, although it is usually viscid, but over time becomes inspissated and is kneaded into ovoid masses called chondroids. Chondroids occur in approximately 20% of horses with guttural pouch empyema. The condition is most commonly associated with *S. equi* var. *equi* infection and is a recognized sequel to strangles.

**CLINICAL FINDINGS**
These include:

- Purulent nasal discharge
Diseases of the upper respiratory tract

If a horse ingests feed material through the pharyngeal opening into the guttural pouch, sometimes the pharyngeal opening permits aspiration of material into the pouch.7 The pouch can also be flushed through the biopsy port of an endoscope inserted via the nares and coiled end inserted via the nasopharynx. A chondroid is evident as multiple circular radiodensities. Passage of a catheter into the guttural pouch via the pharyngeal opening permits aspiration of fluid for cytology and bacterial culture.

Clinical pathology

Hematological examination may reveal evidence of chronic infection, including a mild leukocytosis, hyperproteinemia, and hyperfibrinogenemia. Fluid from the affected guttural pouch contains large numbers of degenerate neutrophils and occasional intracellular and extracellular bacteria. Bacterial culture yields S. equi in approximately 30% of cases and S. zooepidemicus in approximately 40% of cases.8

Necropsy findings

Lesions of guttural pouch empyema include the presence of purulent material in the guttural pouch and inflammation of the mucosa of the affected guttural pouch.

Diagnostic confirmation

Diagnostic confirmation in a horse with clinical signs of guttural pouch disease is achieved by demonstration of purulent material in the guttural pouch by endoscopic or radiographic examination and examination of the fluid.

Differential diagnosis

Differential diagnosis of guttural pouch empyema includes:
- Abscessation of retropharyngeal lymph nodes
- Guttural pouch tympany
- Guttural pouch mycosis.

Guttural pouch empyema should also be differentiated from other causes of nasal discharge in horses including:
- Sinusitis
- Recurrent airway obstruction (heaves)
- Pneumonia
- Esophageal obstruction
- Dysphagia of other cause.

Infection by Mycobacterium avium complex organisms causes nasal discharge and granulomatous lesions in the guttural pouch.9

Treatment

The principles of treatment are removal of the purulent material, eradication of infection, reduction of inflammation, relief of respiratory distress and provision of nutritional support in severely affected horses.

Removal of purulent material may be difficult but can be achieved by repeated flushing of the affected guttural pouch. The guttural pouch can be flushed through a catheter (10–20 French, 3.3–7.0 mm male dog urinary catheter) inserted as needed via the nares, or a catheter (polyethylene 240 tubing) with a coiled end inserted via the nares and retained in the pouch for several days.7 The pouch can also be flushed through the biopsy port of an endoscope inserted into the guttural pouch.

The choice of fluid with which to flush the guttural pouch is arbitrary but frequently used fluids include normal (isotonic) saline, lactated Ringer’s solution or 1% (w/v) povidone–iodine solution. It is important that the fluid infused into the guttural pouch be nonirritating as hydrogen peroxide or strong solutions of iodine (e.g. 10% w/v povidone–iodine) will exacerbate the inflammation of the mucosa and underlying nerves and can actually prolong the course of the disease.4 The frequency of flushing is initially daily, with reduced frequency as the empyema resolves.

Infusion of antibiotics into the guttural pouch is probably without merit. Because of the viscous nature of the empyema fluid, it is necessary to infuse large volumes of lavage solution (1–2 L) on consecutive days. It may be necessary to treat for 7–10 days. The infusion of acetylcysteine (60 mL of a 20% solution) into the pouch after lavage with 1–2 L of saline has been reported to be effective in aiding the removal of purulent material.5 Removal of chondroids usually requires surgery, although dissection and removal of chondroids through the pharyngeal opening has been described.10 A stone remover inserted through the biopsy channel of the endoscope can be useful for removal of small numbers of chondroids, but is tedious if there are large numbers of them.

Topical application of antimicrobials into the guttural pouch is probably ineffective because they do not penetrate the infected soft tissues of the pouch and retropharyngeal area.

NSAIDs such as flunixin meglumine (1 mg/kg intravenously or orally every 12 h) or phenylbutazone (2.2 mg/kg intravenously or orally every 12 h) are used to reduce inflammation and pain. Severely affected horses may require relief of respiratory distress by tracheotomy. Dysphagic horses may need nutritional support, including administration of fluids.

Chronic cases refractory to treatment might require fistulation of the guttural pouch into the pharynx.11

Control

Prevention of guttural pouch empyema is based on a reduction in the frequency and severity of S. equi infection in horses (see Strangles).

CLINICAL FINDINGS

Epistaxis is usually severe and frequently life-threatening. There is profuse bleeding of bright red blood from both nostrils during an episode, and between episodes there may be a slight, serosanguineous nasal discharge. There are usually several episodes of epistaxis over a period of weeks before the horse dies. Most horses that die of guttural pouch mycosis do so because of hemorrhagic shock.3,4

Signs of cranial nerve dysfunction are common in horses with guttural pouch mycosis and may precede or accompany epistaxis.

- Dysphagia is the most common sign of cranial nerve disease and is attributable to lesions of the glossopharyngeal and cranial laryngeal (vagus) nerves. Dysphagic horses may attempt to eat or drink but are unable to move the food bolus from the oral cavity to the esophagus.
- Affected horses frequently have nasal discharge that contains feed material and often develop aspiration pneumonia.
- Lesions of the recurrent laryngeal nerve cause laryngeal hemiglottis.
- Horner's syndrome (ptosis of the upper eyelid, miosis, enophthalmos and prolapse of the nictitating membrane) is seen when the lesion involves the cranial cervical ganglion or sympathetic nerve trunk.
- Facial nerve dysfunction, evident as drooping of the ear on the affected side, lack of facial expression, inability to close the eyelids, corneal ulceration and deviation of the muzzle away from the affected side, also occurs.

Signs of cranial nerve and sympathetic trunk dysfunction may resolve with eradication of the infection, but are frequently permanent.

Guttural pouch mycosis is also associated with pain on palpation of the parotid region, head shyness and abnormal head position. The infection may spread to the atlanto-occipital joint, causing pain on movement of the head,5 or to the brain, causing encephalitis.6

Endoscopic examination of the guttural pouch reveals a plaque of dark yellow to black necrotic material in the dorsal aspect of the medial compartment. A sample of the material can be collected through a biopsy port of the endoscope and submitted for culture. The mycotic plaque cannot be easily dislodged by manipulation with biopsy instruments or the end of the endoscope. In cases with ongoing or recent hemorrhage, the presence of large quantities of blood may prevent identification of the mycotic plaque. Both pouches should always be examined because of the occasional occurrence of bilateral disease or extension of the disease through the medial septum.

Radiographic examination of the guttural pouches may reveal the presence of a lesion in the appropriate position, but is frequently unrewarding.

CLINICAL PATHOLOGY

There are no characteristic findings on the hemogram, nor are there serum biochemical abnormalities. Horses with repeated hemorrhage may be anemic. Immunoblot may identify the presence of serum antibodies specific for A fumigatus in infected horses,7 although the diagnostic usefulness has not been determined. Culture of a sample of the necrotic tissue will frequently yield one of the causative fungi.

NECROPSY FINDINGS

Lesions of guttural pouch mycosis include the presence of a clearly demarcated, yellow-brown to black, dry plaque of necrotic tissue in the dorsal aspect of the medial compartment of the guttural pouch. The plaque of tissue is firmly adherent to underlying tissues and may perforate the medial septum and invade the other pouch. The infection may involve the adjacent nerves and blood vessels and spread to soft tissues and bone. Histological examination reveals the presence of inflammatory cells in nerves and tissues surrounding the gross lesion. There is chromatolysis and degeneration of neurones in affected nerves. The internal carotid artery may have an aneurysmal dilatation or there may be rupture of the arterial wall without dilatation. There is usually partial thrombosis of the arterial wall.

Differential diagnosis

Differential diagnoses for epistaxis not associated with exercise include ethmoidal hematoma or guttural pouch empyema, neoplasia, rupture of the longus capitis muscle or penetration by a foreign body.

TREATMENT

Prevention of hemorrhage from the internal carotid or maxillary artery is achieved by surgical ligation, transarterial coil embolization or occlusion with intraarterial balloons of one or more of the external carotid, internal carotid or maxillary artery.8,9 Because of the high rate of death from hemorrhage in horses with guttural pouch mycosis, some authors recommend that all affected horses be subjected to surgical ligation of the internal carotid or maxillary artery, or occlusion of the carotid or maxillary arteries immediately after the report of the diagnosis.9,10

Acute hemorrhage is treated by intraarterial thrombolytic therapy or surgical ligation.7

CONTROL

There is no effective control by antifungal therapy or any other antifungal agents.

GUTTURAL POUCH TYPANITY

ETIOLOGY AND EPIDEMIOLOGY

Guttural pouch tympany refers to the gaseous distension of one, rarely both, guttural pouches of young horses. Tympany develops in foals up to 1 year of age but is usually apparent within the first several months of life. Fillies are more commonly affected than are colts by a ratio of 2–4:1. The cause is not known although a polygenic cause has been proposed for Arabians.

CLINICAL FINDINGS

Clinical findings include marked swelling of the parotid region of the affected side with lesser swelling of the contralateral side. The swelling of the affected side is not painful on palpation and is elastic and compressible. There are stertorous breath sounds in most affected foals due to impingement of the distended pouch on the nasopharynx. Respiratory distress may develop. Severely affected foals may be dysphagic and develop aspiration pneumonia.

Endoscopic examination of the pharynx reveals narrowing of the nasopharynx by the distended guttural pouch. The guttural pouch openings are usually normal. There are usually no detectable abnormalities of the guttural pouches apart from distension. Radiographic examination demonstrates air-filled pouches, and dorsoventral images permit documentation of which side is affected. There are no characteristic changes in the hemogram or serum biochemical profile.

There are no characteristic lesions and necropsy examination usually does not demonstrate a cause for the disease.

TREATMENT

Treatment consists of surgical fenestration of the medial septum allowing drainage of air from the affected pouch into the unaffected side. The prognosis for long-term resolution of the problem after surgery is approximately 60%.

CONGENITAL DEFECTS

Primary congenital defects are rare in the respiratory tracts of animals. Hyoplasia of the epiglottis is detected occasionally in horses. Tracheal hypoplasia is recognized in calves and miniature horses. Secondary defects, which are associated with major defects in other systems, are more common. Most of the defects in lambs are associated with defects of the oral cavity, face, and cranial vault. Accessory lungs are recorded occasionally and if their bronchi are vestigial the lungs can present themselves as tumor-like masses occupying most of the chest. Pulmonary hypoplasia is associated with congenital diaphragmatic hernia.

Introduction

Diseases of the urinary system are more common and more important than diseases of the kidneys in farm animals. Occasionally, renal insufficiency develops as a sequel to diseases such as pyelonephritis, embolic nephritis, amyloidosis and nephrosis. A knowledge of the physiology of urinary secretion and excretion is required to properly understand disease processes in the urinary tract. The principles of renal insufficiency presented here are primarily extrapolated from research in other species, particularly human medicine. Although, in general, these principles probably apply to farm animals, the details of renal function and renal failure in farm animals have received only limited study.

Diseases of the reproductive tract are not presented in this book and the reader is referred to textbooks on the subject. Inevitably, some of the reproductive diseases are mentioned in the differential diagnosis of the medical conditions presented here and in circumstances in which the reproductive tract is affected coincidentally. Reference to these entries in the text can be made through the index.

Principles of renal insufficiency

The kidneys excrete the end-products of tissue metabolism (except for carbon dioxide), and maintain fluid, electrolyte and acid–base balance, by varying the volume of water and the concentration of solutes in the urine. It is convenient to think of the kidney as composed of many similar nephrons, the basic functional units of the kidney. Each nephron is composed of blood vessels, the glomerulus and a tubular system that consists of the proximal tubule, the loop of Henle, the distal tubule and the collecting duct.

The glomerulus is a semipermeable filter that allows easy passage of water and low-molecular-weight solutes but restricts passage of high-molecular-weight substances such as plasma proteins. Glomerular filtrate is derived from plasma by simple passive filtration driven by arterial blood pressure. Glomerular filtrate is identical to plasma except that it contains little protein or lipids. The volume of filtrate, and therefore its content of metabolic end-products, depends upon the hydrostatic pressure and the plasma oncotic pressure in the glomerular capillaries and on the proportion of glomeruli which are functional. Because these factors are only partially controlled by the kidney, in the absence of disease, the rate of filtration through the glomeruli is relatively constant.

The epithelium of the tubules actively and selectively reabsorbs substances from the glomerular filtrate while permitting the excretion of waste products. Glucose is reabsorbed entirely, within the normal range of plasma concentration; phosphate is reabsorbed in varying amounts depending upon the needs of the body to conserve it; other substances such as inorganic sulfates and creatinine are not reabsorbed in appreciable amounts. The tubules also actively secrete substances, particularly electrolytes as they function to regulate acid–base balance. As a result of the balance between resorption and secretion, the concentration of solutes in the urine varies widely when the kidneys are functioning normally.

The principal mechanism that regulates water reabsorption by the renal tubules is antidiuretic hormone (ADH). Tissue dehydration and an increase in serum osmolality stimulates secretion of ADH from the posterior pituitary gland. The renal tubules respond to ADH by conserving water and returning serum osmolality to normal, thereby producing a concentrated urine.
Diseases of the kidneys, and in some instances of the ureters, bladder, and urethra, reduce the efficiency of the kidney's functions, resulting in: disturbances in protein, acid–base, solute and water homeostasis and in the excretion of metabolic end-products. A partial loss of function is described as renal insufficiency. When the kidneys can no longer regulate body fluid and solute composition, renal failure occurs.

RENAI INSUFFICIENCY AND RENAL FAILURE

Renal function depends upon the number and functionality of the individual nephrons. Insufficiency can occur from abnormalities in:

- The rate of renal blood flow
- The glomerular filtration rate
- The efficiency of tubular reabsorption.

Of these three abnormalities, the latter two are intrinsic functions of the kidney, whereas the first depends largely on vasomotor control which is markedly affected by circulatory emergencies such as shock, dehydration, and hemorrhage. Circulatory emergencies may lead to a marked reduction in glomerular filtration but they are extrarenal in origin and cannot be considered as true causes of renal insufficiency. However, prolonged circulatory disruption can cause renal ischemia and ultimately renal insufficiency.

Glomerular filtration and tubular reabsorption can be affected independently in disease states and every attempt should be made to clinically differentiate glomerular disease from tubular disease. This is because the clinical and clinicopathological signs of renal dysfunction depend on the anatomical location of the lesion and the imbalance in function between glomeruli and tubules. Renal dysfunction tends to be a dynamic process so the degree of dysfunction varies with time. If renal dysfunction is so severe that the animal’s continued existence is not possible it is said to be in a state of renal failure and the clinical syndrome of uremia will be present.

CAUSES OF RENAL INSUFFICIENCY AND UREMIC

The causes of renal insufficiency, and therefore of renal failure and uremia, can be divided into prerenal, renal, and postrenal groups.

Prerenal causes include congestive heart failure and acute circulatory failure, either cardiac or peripheral, in which acute renal ischemia occurs in response to a decrease in renal blood flow. Proximal tubular function is affected by renal ischemia to a much greater extent than the glomerulus or distal tubules; this is because of the high metabolic demands of the proximal tubules. However, those parts of the tubules within the medulla are particularly susceptible to hypoxic damage because of the low oxygen tension in this tissue, the dependency of blood flow on glomerular blood flow and the high metabolic rate of this tissue. Renal medullary necrosis is a direct consequence of these factors. In ruminants, severe bloat can interfere with cardiac output and lead to renal ischemia.

Renal causes include glomerulonephritis, interstitial nephritis, pyelonephritis, embolic nephritis and amyloidosis. Acute renal failure can be produced in any of the farm animal species by administration of a variety of toxins (see Toxic nephrosis, below). The disease can also occur secondary to sepsis and hemorrhagic shock. Experimental uremia has also been induced by surgical removal of both kidneys but the results, especially in ruminants, are quite different from those in naturally occurring renal failure. The clinical pathology is similar but there is a prolonged period of normality after the surgery.

Postrenal uremia may also occur, specifically complete obstruction of the urinary tract by vesical or urethral calculus, or more rarely by bilateral urethral obstruction. Internal rupture of any part of the urinary tract, such as the bladder, ureters, or urethra, will also cause postrenal uremia.

PATHOGENESIS OF RENAL INSUFFICIENCY AND RENAL FAILURE

Damage to the glomerular epithelium destroys its selective permeability and permits the passage of plasma proteins into the glomerular filtrate. The predominant protein is initially albumin, because of its negative charge and a lower molecular weight than globulins; however, with advanced glomerulonephritis (such as renal amyloidosis) all plasma proteins are lost. Glomerular filtration may cease completely when there is extensive damage to glomeruli, particularly if there is acute swelling of the kidney, but it is believed that anuria in the terminal stages of acute renal disease is caused by back diffusion of all glomerular filtrate through the damaged tubulal epithelium rather than failure of filtration. When renal damage is less severe, the remaining nephrons compensate to maintain total glomerular filtration by increasing their filtration rates. When this occurs, the volume of glomerular filtrate may exceed the capacity of the tubular epithelium to reabsorb fluid and solutes. The tubules may be unable to achieve normal urine concentration. As a result, an increased volume of urine with a constant specific gravity is produced and solute diuresis occurs. This is exacerbated if the tubular function of the compensating nephrons is also impaired. The inability to concentrate urine is clinically evident as polyuria and is characteristic of developing renal insufficiency.

Decreased glomerular filtration also results in retention of metabolic waste products such as urea and creatinine. Although marked increases in serum urea concentration are probably not responsible for the production of clinical signs, because urea readily crosses cell membranes and is an effective osmole, the serum urea concentration can be used to monitor glomerular filtration rate. However, the utility of serum urea concentration as a measure of glomerular filtration rate is reduced because serum urea concentrations are influenced by the amount of protein in the diet, by hydration and by gastrointestinal metabolism of urea. Serum urea concentrations are higher in animals on high-protein diets and dehydation increases serum urea concentration by increasing resorption of urea in the loop of Henle, independent of effects of hydration of glomerular filtration rate. Urea is excreted into saliva of ruminants and metabolized by ruminal bacteria. In contrast, creatinine is excreted almost entirely by the kidney, creatine originates from breakdown of creatine phosphate in muscle, and serum concentrations of creatinine are a useful marker of glomerular filtration rate. The relationship between serum creatinine concentration and glomerular filtration rate is hyperbolic - a reduction in glomerular filtration rate by half results in a doubling of the serum creatinine concentration. Phosphate and sulfate retention also occurs when total glomerular filtration is reduced and sulfate retention contributes to metabolic acidosis in renal insufficiency. Phosphate retention also causes a secondary hypocalemia, due in part to an increase in calcium excretion in the urine. In horses, the kidneys are an important route of excretion of calcium so the decreased glomerular filtration rate present in horses with chronic renal failure can result in hypercalcemia. Variations in serum potassium levels also occur and appear to depend on potassium intake. Hyperkalemia can be a serious complication in renal insufficiency in humans, where it is one of the principal causes of the myocardial asthenia and fatal heart failure that occur in uremia in this species.

Loss of tubular resorptive function is evidenced by a continued loss of sodium and chloride; hyponatremia and hypochloremia eventually occur in all cases of
renal failure. The continuous loss of large quantities of fluid due to solute diuresis can cause clinical dehydration. More often it makes the animal particularly susceptible to dehydration when there is an interruption in water availability or when there is a sudden increase in body water loss by another route – as in diarrhea.

The terminal stage of renal insufficiency – renal failure – is the result of the cumulative effects of impaired renal excretory and homeostatic functions. Continued loss of large volumes of dilute urine causes dehydration. If other circulatory emergencies arise, acute renal ischemia might result, leading to acute renal failure. Prolonged hypoproteinemia results in rapid loss of body condition and muscle weakness. Metabolic acidosis is also a contributing factor to muscle weakness and mental attitude. Hyponatremia and hyperkalemia cause skeletal muscle weakness and myocardial asthenia. Hypercalcemia may be sufficient to contribute to circulatory failure and to nervous signs. All these factors play some part in the production of clinical signs of renal failure, which are typically manifest as weakness, lethargy, inappetence and, with extensive glomerular lesions, dependent edema due to hypoproteinemia. In some cases one or other of them might be of major importance so the clinical syndrome is variable and is rarely diagnostic for renal failure. Bleeding diathesis can also be present in severely uremic animals and has been associated with a lack of antithrombin (a small protein readily lost through the damaged glomerulus), platelet factor 3, platelet dysfunction or disseminated intravascular coagulation.

Renal failure is seen as the clinical state of uremia. It is characterized biochemically by an increase in blood levels of urea and creatinine (azotemia) and by retention of other solutes as described above. Uremia can also occur in urinary tract obstruction.

**Clinical features of urinary tract disease**

The major clinical manifestations of urinary tract disease are:

- Abnormal constituents of urine
- Variations in daily urine flow
- Abdominal pain, painful urination (dysuria) and difficult urination (dysuria and stranguria)
- Abnormal size of kidneys
- Abnormalities of the bladder and urethra
- Acute and chronic renal failure.

**ABNORMAL CONSTITUENTS OF THE URINE**

**Proteinuria**

Proteinuria can be prerenal, renal, or post renal in origin. **Prerenal proteinuria** is due to an abnormal plasma content of proteins that traverse glomerular capillary walls, with the proteins having normal permeselectivity properties (such as hemoglobin, myoglobin, immunoglobulin light chains). **Renal proteinuria** is due to abnormal renal handling of normal plasma proteins, and is functional or pathological. **Functional renal proteinuria** is mild and transient as a result of altered renal physiology during or in response to a transient phenomenon, such as high-intensity exercise or fever. **Pathological renal proteinuria** is due to structural or functional lesions within the kidney, regardless of their magnitude or duration. There are three subcategories of pathological renal proteinuria: glomerular, which is due to lesions altering the permeselectivity properties of the glomerular capillary wall; tubular, which is due to lesions that impair tubular recovery of plasma proteins that ordinarily traverse glomerular capillary walls having normal permeselectivity properties (typically low-molecular-weight proteins); and interstitial, which is due to inflammatory lesions or disease processes (such as acute interstitial nephritis) that result in exudation of proteins from the peritubular capillaries into the urine. **Postrenal proteinuria** is due to entry of protein into the urine after it enters the renal pelvis, and is urinary or extranephric. **Urinary postrenal proteinuria** is due to the entry of proteins derived from hemorhagic or edematous processes affecting the renal pelvis, ureter, urinary bladder, and urethra. **Extrarenal postrenal proteinuria** is due to entry of proteins derived from the genital tract or external genitalia during voiding or in the process of collecting urine for analysis.

Normal urine contains only small amounts of protein that are insufficient to be detected using standard tests. It should be noted that the highly alkaline urine produced by herbivores produces a false-positive reaction (trace 1+) for protein on urine dipstick tests. Prerenal proteinuria may be present in hemoglobinuria and myoglobinuria. Functional renal proteinuria is observed in normal foals, calves, kids, and lambs in the first 40 hours after they receive colostrum. Pathological renal or postrenal proteinuria and hematuria may be present when urinary tract infections are present. Postparturient cows usually have protein present in a free-catch urine sample as a result of washout of uterine fluids; this is a classic example of extra-urinary postrenal proteinuria. Demonstration that proteinuria originates in the kidney is easier if elements that form in the kidney, such as tubular casts, are also present in the urine, or morphological abnormalities of the kidneys are palpable per rectum or identified ultrasonographically.

Proteinuria is most accurately quantified by determining the amount of protein passed in a 24-hour period, which is impractical in clinical cases. Proteinuria is more easily quantified by indexing the protein concentration to creatinine concentration in single urine sample; this has been shown to provide an accurate representation of 24-hour protein loss in the urine.

Chronic pathological renal proteinuria may cause hypoproteinemia as in chronic glomerulonephritis and acute tubular necrosis in horses and in amyloidosis of cattle. When proteinuria originates from pyelonephritis or cystitis other clinical and clinicopathological evidence of these diseases is usually present.

**casts**

Casts are organized, tubular structures that vary in appearance depending on their composition. They occur only when the kidney is involved in the disease process. Casts are present as an indication of inflammatory or degenerative changes in the kidney, where they form by agglomeration of desquamated cells and Tamm-Horsfall protein. Casts may not form in all cases of renal disease. In addition, casts readily dissolve in alkaline urine and are best detected in fresh urine samples.

Erythrocytes, leukocytes, and epithelial cells in urine may originate in any part of the urinary tract.

**Hematuria**

Hematuria can result from prerenal causes when vascular damage occurs, such as trauma to the kidney, septicemia and purpura hemorrhagica. Renal causes include acute glomerulonephritis, renal infarction, embolism of the renal artery, tubular damage as caused by toxic insult, and pyelonephritis. Postrenal hematuria occurs particularly in urolithiasis and cystitis. A special instance of hematuria is enzootic hematuria of cattle when hemorrhage originates from tumors of the urinary bladder. Hematomas of the bladder wall (cystic hematoma) cause hematuria in neonatal foals. Typically, lesions of the kidney, bladder, and proximal urethra cause hemorrhage throughout or towards the end of urination, whereas lesions of the middle and distal urethra are responsible for bleeding at the beginning of urination.

In severe cases of hematuria blood may be voided as grossly visible clots but
more commonly it causes a deep red to brown coloration of the urine. Less severe cases may show only cloudiness that settles to form a red deposit on standing. The hematuria may be so slight that it is detectable only on microscopic examination of a centrifuged sediment. In females, free-flow urine samples may be contaminated by blood from the reproductive tract; it may therefore be necessary to collect a sample by catheterization to avoid the chance of contamination of the urine occurring in the vagina.

Blood in urine gives positive results on biochemical tests for hemoglobin and myoglobin. Because red blood cells can be lysed in dilute urine, red-colored urine should be examined microscopically for the presence of erythrocytes. The presence of a heavy brown deposit is not sufficient basis for a diagnosis of hematuria as this may also occur in hemoglobinuria. If the bladder or urethra are involved in the process that causes hematuria, abnormalities may be detectable on physical examination. Gross hematuria persisting for long periods may result in severe blood loss anemia. Severe urinary tract hemorrhage of undetermined origin in aged mares has been recorded. The syndrome is widely recognized, though not well documented, in Arabian mares. Endoscopic examination reveals hemorrhage in one ureter but ultrasonographic examination of the kidneys does not reveal any significant abnormalities. Surgical removal of the affected kidney is not recommended, as the hemorrhage sometimes recurs in the remaining kidney. Treatment is nonspecific. Severe hematuria can also occur in horses with pyleonephritis.

Hemoglobinuria
False hemoglobinuria can occur in hematuria when erythrocytes are lysed and release their hemoglobin. In this case, erythrocytes can be detected only by microscopically examining urine sediment for cellular debris.

True hemoglobinuria causes a deep red to brown coloration of urine and gives a positive reaction to biochemical tests for hemoglobin. There is no erythrocyte debris in sediment. Dipstick tests for proteinuria may not be positive unless the concentration of hemoglobin is very high. There are many causes of intravascular hemolysis, the source of hemoglobinuria. The specific causes are listed under Hemolytic anemia.

Normally, hemoglobin liberated from circulating erythrocytes is converted to bile pigments in the cells of the reticuloendothelial system. If hemolysis exceeds the capacity of this system to remove the hemoglobin, it accumulates in the blood until it exceeds a certain renal threshold and then passes into the urine. Some hemoglobin is reabsorbed from the glomerular filtrate by the tubular epithelium, but probably not in sufficient amounts to appreciably affect the hemoglobin content of the urine. Hemoglobinuria will only be present when the plasma concentration exceeds the renal threshold. Consequently hemoglobin is grossly visible in plasma by the time hemoglobinuria is visible. Hemoglobin precipitates to form casts in the tubules, especially if the urine is acidic, and as a result some plugging of tubules occurs, but the chief cause of uremia in hemolytic anemia is ischemic tubular nephrosis.

Myoglobinuria
The presence of myoglobin (myoglobin) in the urine is evidence of severe muscle damage. The only notable occurrence in animals is azoturia of horses. Myoglobinuria does not occur commonly in enzootic muscular dystrophy, possibly because there is insufficient myoglobin in the muscles of young animals. The myoglobin molecule (molecular weight 16 500) is much smaller than hemoglobin (molecular weight 64 000) and passes the glomerulus much more readily, so a detectable dark brown staining of the urine occurs without very high plasma levels of myoglobin. Detectable discoloration of the serum does not occur as in hemoglobinemia. Inherited congenital porphyria is the other disease that causes a red-brown discoloration of urine. In porphyria, the plasma is also normal in color, but urine porphyria is differentiated from myoglobinuria on the basis of a negative reaction to the guaiac test and the characteristic spectrograph. The porphyrins in inherited congenital porphyria are the only pigments that fluoresce under ultraviolet light.

The presence and type of pigment in the urine can be determined accurately by spectrographic examination, but this is rarely clinically available. Myoglobinuria is usually accompanied by clinical signs and clinical biochemistry abnormalities of acute myopathy, and clinical differentiation of myoglobinuria from hemoglobinuria is usually made on the basis of the clinical signs and serum biochemical findings, including measurement of muscle-derived enzymes such as creatine kinase. As with hemoglobin, myoglobin can precipitate in tubules and may contribute to uremia.

Pyuria
Leukocytes or pus in urine indicates inflammatory exudation at some point in the urinary tract, usually the renal pelvis or bladder. Pyuria may occur as grossly visible clots or shreds, but is often detectable only by microscopic examination of urine sediment. Individual cells and leukocytic casts may be present. Pyuria is usually accompanied by the presence of bacteria in urine.

Bacteriuria
Diagnosis of urinary tract infection is based on finding a clinically relevant bacteriuria in urine collected by free catch (midstream collection into a sterile container), catheterization or cystocentesis. In horses and adult cattle, collection of urine is limited to free catch and catheterization, because the size of the animal and intrapelvic position of the bladder prevent cystocentesis. In contrast, cystocentesis can be performed under ultrasonographic guidance in calves, small ruminants, and pigs. When culturing a urine sample obtained by catheterization, the first 20 mL or so should be discarded because of the potential for contamination from vaginal or distal urethral flora.

Reference values for urine bacterial concentrations are available for the horse; marked bacteriuria suggestive of bacterial infection may be defined as more than 40 000 colony forming units (cfu)/mL from free-catch specimens, and more than 1000 cfu/mL from catheterized specimens.

Crystalluria
Crystalluria should not be overinterpreted in farm animals. Crystals in the urine of herbivorous animals have no special significance unless they occur in very large numbers and are associated with clinical signs of irritation of the urinary tract. Calcium carbonate and triple phosphate crystals are commonly present in normal urine. If they occur in large numbers, it may suggest that the urine is concentrated and indicate the possible future development of urolithiasis. The presence of calcium carbonate crystals in the peritoneal fluid of a neonatal foal has been used to confirm a diagnosis of ruptured bladder.

Glucosuria
Glucosuria in combination with ketonuria occurs only in diabetes mellitus, an extremely rare disease in ruminants. Glucosuria might occur in association with enterotoxemia due to Clostridium perfringens type D and can occur after parenteral treatment with dextrose solutions, adrenocorticotropic hormones or glucocorticoid analogs. Horses with tumor of the pars intermedia of the pituitary gland often have glucosuria. Glucosuria occurs also in acute tubular nephrosis as a result of failure of tubular resorption.

Ketonuria
Ketonuria is a more common finding in ruminants, occurring in starvation,
acetonemia of cattle and pregnancy toxemia of ewes and does. A small amount of ketonuria is normally present in dairy cows in early lactation. As a result, it is important that the assay method used to demonstrate ketonuria is appropriate for urine, since there may be a risk for false-positive reactions on some tests. The standard test is sodium nitroprusside, which turns an intense purple color in the presence of acetocetate, one of the three ketoacids.

VARIATIONS IN DAILY URINE FLOW

An increase or decrease in urine flow is often described in animals, but accuracy demands physical measurement of the amount of urine voided over a 24-hour period. This is not usually practicable in large-animal practice and it is often necessary to guess whether the flow is increased or decreased. Accurate measurement of the amount of water consumed is often easier. Care should be taken to differentiate between increased daily flow and increased frequency without increased flow. The latter is much more common. Decreased urine output rarely if ever presents as a clinical problem in agricultural animals.

Normal urine production is highly variable in large animals and is dependent to a large extent on diet, watering systems and the palatability of the water. Pregnant mares housed in tie stalls consume approximately 53 ± 6.2 (SD) mL of water per kilogram body weight (BW) per day, of which 50 ± 8 mL/kg is from drinking water with the remainder being water in feed. However, most of this water is excreted in the feces with fecal and urinary water excretion being 33.5 ± 8 (mL/kg)/d and 7.6 ± 2 (mL/kg)/d, respectively. Neonatal foals produce urine at an average rate of 150 (mL/kg)/d. Polyuria

Polyuria occurs when there is an increase in the volume of urine produced. Polyuria can result from extrarenal causes as when horses habitually drink excessive quantities of water (psychogenic polydipsia) and, much less commonly, in central diabetes insipidus, when there is inappropriate secretion of antidiuretic hormone (ADH) from the pituitary. Polyuria occurs in horses with tumors of the pars intermedia of the pituitary gland. Although the cause of the polyuria is not known it might be secondary to osmotic diuresis associated with the glucosuria, or to central diabetes insipidus. Central diabetes insipidus is reported in sibling colts. It is extremely rare in other species but has been reported in a ram and a cow. Another extrarenal cause is administration of diuretic drugs including corticosteroids.

Kidney disease results in polyuria when the resorptive capacity of the remaining tubules is exceeded. Polyuria can also occur when the osmotic gradient in the renal medulla is not adequate to produce concentrated urine. Nephrogenic diabetes insipidus causes polyuria because the tubules fail to respond to ADH.

When polyuria is suspected, a urine sample should be collected to determine specific gravity or osmolality. If urine is isosthenuric with a constant specific gravity of 1.008–1.012 (the specific gravity of plasma), then the presence of renal disease should be considered. Serum urea and creatinine concentrations should be determined to evaluate glomerular filtration. If serum urea and creatinine concentrations are within normal limits, a water deprivation test can be performed to assess the animal’s ability to produce concentrated urine.

Oliguria and anuria

Reduction in the daily output (oliguria) and complete absence of urine (anuria) occur under the same conditions and vary only in degree. In dehydrated animals, urine flow naturally decreases in an effort to conserve water as plasma osmolality pressure increases. Congestive heart failure and peripheral circulatory failure may cause such a reduction in renal blood flow that oliguria follows. Complete anuria occurs most commonly in urethral obstruction, although it can also result from acute tubular nephrosis. Oliguria occurs in the terminal stages of all forms of nephritis. Anuria and polyuria lead to retention of solutes and disturbances of acid–base balance that contribute to the pathogenesis of uremia.

Pollakiuria

This is an abnormally frequent passage of urine. Pollakiuria may occur with or without an increase in the volume of urine excreted and is commonly associated with disease of the lower urinary tract such as cystitis, the presence of calculi in the bladder, urethritis and partial obstruction of the urethra. Other causes of pollakiuria include equine herpesvirus infection, sorghum cystitis and neuritis of the cauda equina in horses, neoplasia, obstructive lesions and trauma to the urethra, abnormal vaginal conformation and urachal infection.

Dribbling is a steady, intermittent passage of small volumes of urine, sometimes precipitated by a change in posture or increase in intra-abdominal pressure, reflecting inadequate or lack of sphincter control. Dribbling occurs in large animals with incomplete obstructive urolithiasis and from persistent urachus.

Persistent urachus (also called pervious or patent urachus). Failure of the urachus to obliterate at birth causes urine to dribble from the urachus continuously. Urine may also pass from the urethra. Retrograde infection from omphalitis is common, resulting in cystitis.

Abnormalities of micturition are classified as neurogenic or non-neurogenic. Micturition is mediated principally by the pelvic and pudendal nerves through lumbosacral spinal cord segments under the involuntary control of centers in the brain stem and voluntary control of the cerebrum and cerebellum. Reported neurogenic causes of urinary incontinence in horses include cauda equine neuritis, herpesvirus 1 myelitis, Sudan grass toxicosis, sorghum poisoning, trauma, and neoplasia. Non-neurogenic causes of urinary incontinence in horses include ectopic ureter, cystitis, urolithiasis, hypoglycemia, and abnormal vaginal conformation.

ABDOMINAL PAIN, PAINFUL AND DIFFICULT URINATION (DYSURIA AND STRANGURIA)

Abdominal pain and painful urination (dysuria) and difficult and slow urination (stranguria) are manifestations of discomfort caused by disease of the urinary tract. Acute abdominal pain from urinary tract disease occurs only rarely and is usually associated with sudden distension of the renal pelvis or ureter, or infarction of the kidney. None of these conditions is common in animals, but occasionally cattle affected with pyelonephritis may have short episodes of acute abdominal pain due to either renal infarction or obstruction of the pelvis by necrotic debris. During these acute attacks of pain, the cow may exhibit downward arching of the back, paddling with the hind feet, rolling and bellowing. Abdominal pain from urethral obstruction and distension of the bladder is manifested by tail-switching, kicking at the belly and repeated straining efforts at urination accompanied by grunting. Horses with acute tubular nephrosis following vitamin K administration might show renal colic with arching of the back, backing into corners and rubbing of the perineum and tail head.

Dysuria or painful/difficult urination occurs in cystitis, vesical calculi, and urethritis and is manifested by the frequent passage of small amounts of urine. Grunting may occur with painful urination and the animal may remain in the typical posture after urination is completed. Differentiating pain caused by urinary disease from pain due to other causes depends largely upon the presence
of other signs indicating urinary tract involvement.

**Stranguria** is slow and painful urination associated with disease of the lower urinary tract including cystitis, vesical calculus, urethral obstruction, and urethritis. The animal strains to pass each drop of urine. Groaning and straining may precede and accompany urination when there is urethral obstruction. In urethritis, groaning and straining occur immediately after urination has ceased and gradually disappear and do not recur until urination has been repeated.

**Urine scalding of the perineum or urinary burn** is caused by frequent wetting of the skin with urine. It may be the result of urinary incontinence or the animal's inability to assume normal posture when urinating.

**MORPHOLOGICAL ABNORMALITIES OF KIDNEYS AND URETERS**

Enlargement or decreased size of kidneys may be palpable on rectal examination or detected by ultrasonography. In cattle, gross enlargement of the posterior aspect of the left kidney may be palpable in the right upper flank. Abnormalities of the kidneys such as hydronephrosis in cattle may also be palpable on rectal examination. Increases in the size of the ureter may be palpable on rectal examination and indicate ureteritis or hydrourétér.

**PALPABLE ABNORMALITIES OF THE BLADDER AND URETHRA**

Abnormalities of the bladder that may be palpable by rectal examination include: gross enlargement of the bladder, rupture of the bladder, a shrunken bladder following rupture, and palpable abnormalities in the bladder such as cystic calculi. Abnormalities of the urethra include: enlargement and pain of the pelvic urethra and its external aspects in male cattle with obstructive urolithiasis, and obstruction of the urethral process of male sheep with obstructive urolithiasis.

**ACUTE AND CHRONIC RENAL FAILURE**

The clinical findings of urinary tract disease vary with the rate of development and stage of the disease. In most cases, the clinical signs are those of the initiating cause. In horses, mental depression, colic, and diarrhea are common with oliguria or anuria. In most cases, the clinical signs are those of the initiating cause. In horses, mental depression, colic, and diarrhea are common with oliguria or anuria. The respiration is usually increased in rate and depth but is dyspneic; in the terminal stages it may become periodic in character. The heart rate is markedly increased because of terminal dehydration and myocardial asthenia but the temperature remains normal except in infectious processes and some cases of acute tubular nephropathy. An ammoniacal or uniferous smell on the breath is often described but is usually undetectable. Uremic encephalopathy occurs in a small proportion of cattle and horses with chronic renal failure.15 The animal becomes recumbent and comatose in the terminal stages. The temperature falls to below normal and death occurs quietly, the whole course of the disease having been one of gradual intoxication. Necropsy findings, apart from those of the primary disease, are nonspecific and include degeneration of parenchymatous organs, sometimes accompanied by emaciation and moderate glycosuria. There are rare reports of encephalopathy caused by renal insufficiency.16

Uremia has been produced experimentally in cattle by bilateral nephrectomy and urethral ligation.17,18 There is a progressive increase in serum urea concentration (mean daily increase of 53 mg/dL), serum creatinine concentration (mean daily increase of approximately 3.5 mg/dL), and serum uric acid concentration. Similar findings are reported in prerenal uremia in cattle. Interestingly, serum phosphate and potassium concentrations were for the most part unchanged because of increased salivary secretion, and metabolic acidosis was not evident. Serum potassium concentrations were mildly increased after 5–7 days of bilateral nephrectomy.

**UREMIA**

Uremia is the systemic state that occurs in the terminal stages of renal insufficiency.

Anuria or oliguria may occur with uremia. Oliguria is more common unless there is complete obstruction of the urinary tract. Chronic renal disease is usually manifested by polyuria, but uremia appears in the terminal stages when clinical uremia develops. The uremic animal is depressed and anorectic with muscular weakness and tremor. In chronic uremia, the body condition is poor, probably as a result of continued loss of protein in the urine, dehydration and anorexia. The uremic body condition is poor, probably as a result of continued loss of protein in the urine, dehydration and anorexia. When symptoms are present, the animal is depressed and anorectic with muscular weakness and tremor. The uremic condition is poor, probably as a result of continued loss of protein in the urine, dehydration and anorexia. When symptoms are present, the animal is depressed and anorectic with muscular weakness and tremor.

**Special examination of the urinary system**

Lack of accessibility limits the value of physical examination of the urinary tract in farm animals. Rectal examination can be carried out on horses and cattle and is described in Chapter 1. In small ruminants and calves, the urinary system is largely inaccessible to physical examination although the kidneys may be palpated transabdominally.

**URINALYSIS**

Urinalysis is an essential component of the examination of the urinary system. The reader is referred to a textbook of veterinary clinical pathology for details of the biochemical and microscopic examination of the urine. The common abnormalities of urine are discussed under manifestations of diseases of the urinary system.

**COLLECTION OF URINE SAMPLES**

Collection of urine samples can be difficult. Free flow and catheterized samples are equally useful for routine urinalysis. Horses will often urinate a short time after they are walked into a freshly bedded box stall. Cows urinate if they are relaxed and have their perineum and vulval tip massaged upwards very gently, without touching the tail. Steers and bulls may urinate if the preputial orifice is massaged and splashed with warm water. Ewes often urinate immediately after rising if they have been recumbent for some time. Occluding their nostrils and threatening asphyxia may also induce urination just as they are released and allowed to breathe again; however, this is a stressful procedure and should not be performed in sick or debilitated sheep. An intravenous injection of furosemide (0.5–1.0 mg/kg BW) produces urination in most animals in about 20 minutes. The sample is useful for microbiological examination but its composition has been drastically altered by the diuretic. Diuretics should be used with extreme caution in dehydrated animals.

**CATHETERIZATION OF THE BLADDER**

Urine samples obtained by catheterization are preferred for microbiological examination. Rams, boars, and young calves usually cannot be catheterized because of the presence of a suburethral diverticulum19 and the small diameter of the urethra. A precurred catheter and fluoroscopic guidance can be used to facilitate catheterization of rams and bucks.19 Ewes and sows have vulvas that are too small to allow access to the urethra. Cows can be catheterized relatively simply provided that a fairly rigid, small-diameter (0.5 cm) catheter is used. A finger can be inserted
into the suburethral diverticulum to direct the tip of the catheter over the diverticulum and into the external urethral orifice. Mares can be catheterized easily, either by blindly passing a rigid catheter into the external urethral orifice or by using a finger as a guide for a flexible catheter. Male horses can also be catheterized easily if the penis is relaxed. When urethral obstruction is present the penis is usually relaxed, but administration of an ataractic drug (acepromazine is often used) makes manipulation of the penis easier and often results in its complete relaxation. Because of the long urethra, the catheter must be well lubricated. The catheter should be rigid enough to pass through the long urethra but flexible enough to pass around the ischial arch. In all species, catheterization overcomes the natural defense mechanisms that prevent infectious organisms from ascending the urinary tract. As a result, attention to hygiene during catheterization is essential.

**TESTS OF RENAL FUNCTION AND DETECTION OF RENAL INJURY**

The simplest and most important test of urinary function is the determination of whether or not urine is being voided. This can be accomplished in large animals by restraining them on a clean, dry floor which is examined periodically. Placing an absorbent cloth under recumbent foals and calves will also help determine if urine is being passed.

Renal function tests evaluate the functional capability of the kidney and, in general, assess blood flow to the kidneys, glomerular filtration and tubular function. These tests depend on whether they are based on the examination of serum, urine or both, and assess either function or the presence of injury. The most practical screening tests for the presence of decreased renal function are determination of serum creatinine concentration and urine specific gravity. Determination of both assists differentiation of renal azotemia from prerenal azotemia. In prerenal azotemia, tubular function remains intact and renal conservation of water is optimized, resulting in the production of a concentrated urine. Animals with prerenal azotemia therefore have increased serum concentrations of creatinine and urea, and increased urine specific gravity. For comparison, animals with some degree of renal azotemia have increased serum concentrations of creatinine and urea and a lower than expected value for urine specific gravity. Determination of urine specific gravity should therefore be routinely performed in all dehydrated animals before the initiation of treatment, because oral or intravenous fluid therapy will directly change urine specific gravity.

**Tests of urine**

Urine samples for analysis should be collected by midstream voiding, or cystocentesis in small male ruminants. Bethanechol (0.075 mg/kg subcutaneously) has occasionally been used to produce urine in reluctant individuals, but a spontaneously voided sample is preferred for initial screening. The sample should be centrifuged and the supernatant should be used for laboratory analysis and the sediment and remaining supernatant for routine urine analysis.

**Specific gravity**

Specific gravity of urine is the simplest test to measure the capacity of renal tubules to conserve fluid and excrete solute. For most species, the normal specific gravity range is 1.015–1.035, and in azotemic animals, specific gravity should be greater than 1.020 if the azotemia is prerenal in origin. In chronic renal disease the urine specific gravity decreases to 1.008–1.012 and is not appreciably altered by either deprivation of water for 24 hours or the administration of large quantities of water by stomach tube. It is important to recognize that a specific gravity of less than 1.008 indicates that the kidney can produce a dilute urine and, if sustained, indicates better renal function than a fixed urine specific gravity of 1.008–1.012.

Specific gravity can be inaccurate when other refractive particles are present in urine, such as glucose or protein. Urine specific gravity should therefore be used with caution in animals with proteinuria or glucosuria. As an alternative to specific gravity, osmolality of a fluid directly measures the concentration of solute in the fluid. Urine osmolality therefore provides a more accurate assessment of the tubule’s ability to conserve or excrete solute than does specific gravity, and is the preferred test of urine concentrating ability for research studies. However, urine specific gravity is sufficiently accurate for clinical use in animals without proteinuria or glucosuria, in that there is a linear relationship between urine specific gravity and osmolality, and that urine specific gravity explains 52% of the variation in urine osmolality, the 95% confidence interval for predicting osmolality from the specific gravity measurement being ± 157 mosmol/kg.

**Enzymuria**

A clinically useful index of tubular injury is determining the gamma-glutamyltransferase (GGT) activity in urine. Most enzymes present in serum have a molecular weight greater than that of albumin and are normally not detectable in the glomerular filtrate; the presence of high-molecular-weight enzymes in urine is called parenchymatous enzymuria. For comparison, the presence of low-molecular-weight enzymes (such as lysozyme) in urine is called tubular enzymuria because damage to the proximal tubule impairs its ability to reabsorb enzymes from the glomerular filtrate.

Most of the GGT activity in urine originates from the luminal brush border of the proximal tubular epithelial cells of the kidney. High levels of GGT activity in the urine result from an increase in the rate of proximal tubular epithelial cell destruction, with GGT being released into the urine during the active phase of tissue destruction; an increase in urine GGT activity therefore reflects parenchymatous enzymuria. The activity of GGT (or other high-molecular-weight enzymes such as β-N-acetylglucosaminidase, β-glucuronidase, N-acetyl-β-glucosaminidase) in urine can therefore be used to detect the presence of proximal tubular epithelial cell damage before the onset of renal dysfunction. GGT is the preferred enzyme to identify the presence of parenchymatous enzymuria because the assay is inexpensive and widely available, and the kidney has the highest content of GGT of any organ in the body, thereby increasing the sensitivity of the test.

Urine GGT activity is frequently indexed to an indicator of urine concentration, such as urine creatinine concentration, in order to correct for denominator effects induced by changes in urine volume, and a GGT:creatinine ratio higher than 25 IU/g creatinine is considered abnormal in the horse. However, it may be more appropriate to calculate the fractional clearance of GGT (which compares the extent of tubular damage to the amount of functioning kidney mass) instead of the urinary GGT to creatinine ratio (which compares the amount of tubular damage to muscle mass). Indexing GGT to creatinine is not physiologically valid because enzymes present in urine are not filtered through the glomerulus; using the urine GGT activity alone therefore appears to be more appropriate. Interestingly, urine GGT activity appears more sensitive as an index of tubular injury than the urine GGT to creatinine ratio in horses and sheep, and appears to be the most sensitive indicator of tubular injury in animals being treated with aminoglycosides.

**Glucosuria**

Glucose is freely filtered by the glomerulus and reabsorbed from the filtrate in the
proximal tubules. Glucosuria in the face of a normal serum glucose concentration therefore indicates the presence of abnormal proximal tubular function. Glucosuria occurs early in the development of aminoglycoside-induced proximal tubule nephropathy, and may provide a useful inexpensive and practical screening test for nephrotoxicity in animals without hyperglycemia.26

Proteinuria
Urine protein concentrations in animals without lower urinary tract disease or hematuria are normally much lower than serum protein concentrations and similar to cerebrospinal fluid protein concentration. Glomerular filtrate normally contains low concentrations of low-molecular-weight proteins such as β2-microglobulin (molecular weight 11 800) and lysozyme (molecular weight 14 400). This is because the healthy glomerulus excludes high-molecular-weight proteins such as albumin (molecular weight 65 000) and globulins from the glomerular filtrate, normally functioning proximal tubules reabsorb these low-molecular-weight proteins, leading to very low urine protein concentrations. Alterations in tubular function can therefore lead to proteinuria, but typically glomerular injury produces much larger increases in urine protein concentration than those produced by altered proximal tubule function.

Determination of urine protein concentrations requires a sensitive analytical test, such as the Coomassie brilliant blue method. Urinary protein concentrations may be indexed to the urine creatinine concentration in order to account for denominator effects of changes in urine volume. Dividing the urinary protein concentration (mg/dL) by the creatinine concentration (mg/dL) produces a unitless ratio, which provides a sensitive and reliable diagnostic method for the detection and quantification of proteinuria.28 In general, increased urinary concentrations of albumin and β2-microglobulin indicate glomerular proteinuria and tubular proteinuria, respectively. Proteinuria is massive and sustained in cattle and sheep with advanced renal amyloidosis and animals with advanced glomerulonephritis (glomerular proteinuria) but is mild in animals without glomerular disease but with proximal tubular injury (tubular proteinuria). A urine protein concentration to creatinine concentration ratio of less than 13 is considered to be more indicative of tubular than glomerular proteinuria.29 Microalbuminuria does not appear to have been evaluated as an early and sensitive test of glomerular disease in large animals but increases in urine albumin concentration would be expected in animals with glomerular disease.

Tests of serum
These tests depend on either the accumulation, in cases of renal insufficiency, of metabolites normally excreted by the kidney or the excretion of endogenous substances by the kidney. Determination of serum urea and creatinine concentration are essential components of an evaluation of the urinary system. These serum indices of function are simple estimates of glomerular filtration because urea and creatinine are freely filtered by the glomerulus. Serum concentrations of urea and creatinine do not rise appreciably above the normal range until 60–75% of nephrons are destroyed.

Serum urea and creatinine concentrations are influenced by blood flow to the kidneys and may be increased in prerenal uremia. They also suffer from the disadvantage that their serum concentrations can vary with the rate of protein catabolism and are not dependent only on renal function. In cattle, for example, serum urea concentrations caused by prerenal lesions may be higher than those resulting from renal disease, because salivary secretion of urea, rumen metabolism of urea and decreased feed intake (and therefore decreased protein intake) may lower serum urea concentration in chronic disease.

Creatinine in herbivores is essentially totally derived from endogenous creatine. Creatine is produced by the liver from amino acids and circulates in the plasma before being taken up by skeletal muscle, where it stores energy in the form of phosphocreatine. Creatine is converted to creatinine by a non-enzymatic irreversible process and is distributed throughout the body water. Creatinine is therefore released from skeletal muscle at a constant rate in animals without myonecrosis and is therefore an indirect index of muscle mass; this is the reason why serum creatinine concentrations are highest in intact males, intermediate in adult females and lowest in neonates and cachetic animals. Serum creatinine concentrations are constant within an animal because they reflect muscle mass, which does not change rapidly; an increase in serum creatinine concentration of more than 0.3 g/dL should be considered to be clinically significant.30

Serum creatinine concentration is routinely measured using the Jaffé reaction, in which a colored product is formed from creatinine and picrate in an alkaline solution. However, the alkaline picrate reaction has poor specificity, as it relates to the presence of noncreatine chromogranins in plasma and the tubular secretion of creatinine in some species. Although the renal clearances of inulin or creatinine are the preferred research methods for measuring renal excretory function, these techniques are impractical in clinical patients and male ruminants because they require urethral catheterization, rinsing of the bladder contents and timed urine collections.

Renal excretory function is more practically assessed in clinical patients by measuring the plasma clearance of endogenous creatine. Creatine is produced by the liver from amino acids and circulates in the plasma before being taken up by skeletal muscle, where it stores energy in the form of phosphocreatine. Creatine is converted to creatinine by a non-enzymatic irreversible process and is distributed throughout the body water. Creatinine is therefore released from skeletal muscle at a constant rate in animals without myonecrosis and is therefore an indirect index of muscle mass; this is the reason why serum creatinine concentrations are highest in intact males, intermediate in adult females and lowest in neonates and cachetic animals. Serum creatinine concentrations are constant within an animal because they reflect muscle mass, which does not change rapidly; an increase in serum creatinine concentration of more than 0.3 g/dL should be considered to be clinically significant.30

Tests of urine and serum
Urine osmolality to serum osmolality ratio
A urine:plasma osmolality ratio of 1 indicates isosmotic clearance of materials by the kidney. A ratio less than 1 indicates that the kidneys are diluting the urine, and a ratio more than 1 indicates that the urine is being concentrated. Because the plasma osmolality is much more constant
than urine osmolality, the important clinical factor is whether urine osmolality is less than, equal to, or greater than 300 mosmol/kg. Measurement of urine osmolality requires a dedicated laboratory unit and is rarely indicated in the clinical management of renal disease because of the widespread availability of hand-held refractometers. In fact, measurement of urine osmolality is needed only in research studies.

Water deprivation test
This can be used to assess renal concentrating ability in animals that have isosthenuria with urine specific gravity of 1.008–1.012 but do not have azotemia. Water deprivation tests should not be performed on animals that are already azotemic and should be undertaken with extreme caution and frequent (hourly to 2-hourly) monitoring in animals that are polyuric but not azotemic. Animals that are unable to conserve water because of renal disease can rapidly become dehydrated and develop prerenal uremia as a result.

In brief, the water deprivation test monitors the animal's ability to detect an increase in serum osmolality, release antidiuretic hormone and produce a concentrated urine as a result of the action of antidiuretic hormone on the kidney. The test usually requires documentation that the animal has polyuria and polydipsia, with water consumption greater than cohorts of the same age, lactation stage and diet, when housed under the same conditions. Before conducting the water deprivation test, the animal is weighed and a Foley catheter is placed in the bladder (females), or the animal is housed in a dry stall (males). Access to water is prevented and the urine and serum are tested every 1–2 hours or when voided in males. The test should be stopped when the urine specific gravity increases to more than 1.015–1.020, when there is an increase in serum creatinine concentration of 0.3 g/dL or greater, or when there has been a decrease in body weight of 5% or more.

Animals that concentrate their urine after water deprivation are diagnosed with psychogenic polydipsia and their water availability is gradually decreased. Animals that fail to concentrate their urine after water deprivation are diagnosed with diabetes insipidus; nephrogenic diabetes insipidus can be ruled out if the animal produces a concentrated urine within a few hours of an intramuscular injection of exogenous vasopressin (0.15–0.30 U/kg BW). In the latter case, the diagnosis is nephrogenic diabetes insipidus as a result of inadequate release of antidiuretic hormone. Such cases are extremely rare in large animals and have been attributed to pituitary neoplasia (particularly pituitary adenoma in horses) or encephalitis. Determination of plasma vasopressin and arginine vasopressin concentrations using a radioimmunoassay may assist in differentiation of nephrogenic from neurogenic diabetes insipidus; in the former the plasma vasopressin concentration increases during the water deprivation test. However, because the assay for plasma vasopressin concentration is not widely available and has not been validated for all large animals, the response to exogenous vasopressin is the preferred clinical test for differentiating nephrogenic from neurogenic diabetes insipidus. Two related horses have been diagnosed with nephrogenic diabetes insipidus, suggesting that this may be inherited as an X-linked disorder.

Water deprivation tests are not needed if urine specific gravity is below 1.008, because the presence of hyposthenuria indicates that tubular function is acting to conserve solute and produce dilute urine. In other words, a specific gravity below 1.008 is a better clinical sign than a constant specific gravity of 1.008–1.012, because a low specific gravity indicates the presence of some tubular function. Low specific gravity may occur in diabetes insipidus, following excessive water intake or fluid administration, or following diuretic administration. Neonatal animals on fluid diets and lactating dairy cows often produce dilute urine.

Renal clearance studies
In animals with renal disease, serum creatinine and urea nitrogen concentrations are insensitive indicators of renal dysfunction and exceed the upper limit of the reference range only after extensive loss of nephron function. Increases in serum concentrations of creatinine or urea nitrogen cannot be used to distinguish between prerenal, renal, and postrenal azotemia. Urine specific gravity can be used to differentiate prerenal from renal azotemia. However, results of urinalysis do not reflect the magnitude of the disease and they are not specific for specific renal disease.

Calculation of renal clearance of creatinine, urea nitrogen, and electrolytes, along with measurement of specific enzyme activity in the urine, is a more sensitive indicator of damage to the tubules than serum biochemical analysis. Urinary diagnostic indices have been used to evaluate renal function and to detect and estimate the extent of renal damage in adult cattle, calves, horses, and foals. For example, it can be clinically useful to determine the urine to serum concentration, the ratio of urinary creatinine to urea nitrogen, the renal clearance of creatinine and urea nitrogen, the urine to serum osmolality ratio, the urine protein concentration or urine protein to creatinine ratio, the fractional clearances of electrolytes, and urine enzyme activity. Early diagnosis of renal injury facilitates initiation of appropriate treatment and reduces the incidence of irreversible renal failure. Sequential measurement of these indices can aid in the determination of prognosis and allows monitoring and evaluation of the extent of recovery of renal function.

The tests require simultaneous sampling of blood and urine. Samples can also be collected daily for several days and weekly to determine any age-related changes, and these are available for calves from birth to 90 days of age.

Fractional clearance
The fractional clearance from plasma of a given substance is calculated by comparing the amount of the substance excreted in the urine with the amount filtered through the glomerulus. The formula used to calculate fractional clearance of substance X (FCx) is:

\[
FC_x(\%) = \frac{(U_x \times S_x)}{U_x \times (S_x)_{continue}} \times 100\%
\]

where \(U_x\) and \(S_x\) are the urine and serum concentrations of X, respectively, and \((U_x)_{continue}\) and \((S_x)_{continue}\) are the urine and serum concentrations of creatinine, respectively. Fractional clearance has been erroneously called fractional excretion; the latter term is confusing, inappropriate and has no scientific basis. The fractional clearance provides information regarding the action of tubular transport mechanisms on the filtered substances; a value below 100% indicates net reabsorption, whereas a ratio above 100% indicates net secretion.

Sodium and inorganic phosphate are reabsorbed from the glomerular filtrate by the renal tubules; therefore, the fractional clearance of sodium and phosphate provide clinically useful indices of tubular function. Sodium retention is an important proximal tubular function and the fractional clearance of Na is usually less than 1% for animals (and often <0.2%) unless they have a high oral or intravenous sodium intake, when fractional clearance values can be increased to 4%. Renal phosphorus excretion is affected by acid-base status and body calcium and phosphate status and is therefore a less specific indicator of tubular function than fractional clearance of sodium. Values for the fractional clearance of phosphorus normally vary from 0.1–0.4%, although higher values may be seen in ruminants with high phosphate intakes. Typically,
tubular function can be adequately characterized by determining the fractional clearance of sodium alone, or sodium and phosphorus; the fractional clearance of chloride rarely adds useful information in clinical cases because it is highly correlated to the fractional clearance of sodium, and determination of the fractional clearance of potassium is hampered by methodological limitations associated with zwitterion formation in urine. Determination of the fractional clearance of calcium can be useful when dietary intake and metabolism of calcium are being evaluated. Substantial variations in fractional clearance values are present in horses over a 24-hour period as a result of the electrolyte load ingested with feed. Some standardization of the time of urine collection in relationship to feeding is therefore needed in research studies, but is clearly impractical in clinical cases.

Fractional clearance values for a number of electrolytes have been determined for horses, foals, cattle, sheep. Renal clearance, urinary excretion of endogenous substances and urinary diagnostic indices have been measured in healthy neonatal foals. The urine volume of neonatal foals is proportionately greater than that of calves and the normal neonatal foal produces a dilute urine. When compared with normal values in adult horses, fractional clearance of electrolytes was similar for sodium but higher for potassium, phosphorus, and calcium. Renal function in newborn calves is similar to adult cattle within 2–3 days of birth and calves can excrete large load volumes in response to water overload and conserve water in response to water deprivation as efficiently as adult cattle.

Animals with acute renal azotemia have low urinary creatinineserum creatinine and urine nitrogen:serum nitrogen; animals with acute prerenal azotemia have normal to high urinary creatinineserum creatinine and urinary nitrogen:serum nitrogen. However, animals with acute renal azotemia also have a low urine specific gravity relative to the serum creatinine concentration, and it remains to be determined whether measurement of urinary creatinine and urea concentrations and serum urea concentrations provide any more information in clinical cases than that provided by urine specific gravity and serum creatinine concentration.

**Summary of renal function tests**

In summary, the serum creatinine or urea concentration provides a useful screening test for the presence of urinary tract disease, with an increase in serum creatinine concentration of more than 0.3 mg/dL over baseline providing a useful clinical test for the presence of nephrotoxicosis in normally hydrated animals being treated with potentially nephrotoxic agents. Azotemia can be prerenal, renal, or post renal in origin; the cause is most practically differentiated in azotemic animals by measuring the specific gravity of urine before any treatment has been administered. In animals suspected of having urinary tract disease, the urinary protein concentration and protein to creatinine ratio provide clinically useful indices of glomerular and tubular function and injury, the urine specific gravity and fractional clearance of sodium and phosphorus provide clinically useful indices of tubular function in animals not on intravenous or oral fluids and consuming a normal diet, and determination of urine GGT activity and analysis of urine for the presence of casts provide clinically useful and sensitive indices of tubular injury. The results of most other laboratory tests rarely provide additional information in an animal suspected to have urinary tract disease, and are not currently recommended for routine clinical use.

**DIAGNOSTIC EXAMINATION TECHNIQUES**

**Ultrasoundography**

Transcutaneous and transrectal ultrasonography is commonly used to detect and characterize anatomical abnormalities of the kidneys, ureters, bladder, and urethra in horses, cattle, and small ruminants. Ultrasonography is an effective screening test for diagnosing obstructive conditions of the urinary tract, including hydronephrosis, hydrouroureters, and bladder distension, and can be used to visualize the kidney and guide the biopsy needle during renal biopsy. Removal of the haircoat and the use of an ultrasonographic coupling gel assist in obtaining acceptable acoustic coupling, whereas saturation of a foal's haircoat with alcohol or coupling gel may be adequate when clipping is not desirable.

Techniques for ultrasonographic evaluation of the urinary system of the sheep have been described.

**Renal biopsy**

Percutaneous renal biopsy can be carried out in sedated and adequately restrained cows and horses. A coagulation profile should be run before renal biopsy is attempted in animals with severe and chronic renal disease or those animals suspected to have a coagulopathy. Renal biopsy is contraindicated in animals with documented pyelonephritis because of the risk of perirenal abscessation after the biopsy procedure.

The left kidney is usually biopsied because it is more accessible. In cows, the left kidney is moved to the right paralumbar fossa and fixated in position by rectal manipulation. In horses, the left kidney is identified using transabdominal ultrasonography and fixated in position by palpation per rectum. The skin over the biopsy site is aseptically prepared and 5–10 mL of local anesthetic is infiltrated along the proposed track for the biopsy needle. A small stab incision is made in the skin with a scalpel and a renal biopsy sample is collected by introducing a biopsy needle through the abdominal wall and manipulating it into the caudal pole of the kidney. The renal biopsy is fixed in 10% formalin and submitted for examination and histological diagnosis. Biopsy of the caudal pole minimizes the risk of trauma to the renal pelvis, renal artery, and renal vein.

Possible complications of renal biopsy are hemorrhage or abscession in animals with pyelonephritis. Hemorrhage after renal biopsy can be extensive, and is usually perirenal but rarely life threatening. Occasionally, severe hematuria is present for hours after the biopsy procedure, but usually resolves within a few days. Because of the potential for life-threatening sequelae, renal biopsy should
only be performed when the etiology is uncertain and histologic examination will direct treatment, or when an early and accurate prognosis is desired. In animals with acute tubular injury, electron microscopic examination of the basement membrane is required to accurately predict return to normal function.

**Endoscopy**

Transurethral endoscopy can be easily performed in mares, stallions, geldings, and cows in order to examine the urethra and bladder, and flow of urine from both ureters. Horses and cows are sedated and adequately restrained for the procedure. Biopsy of diseased tissue can be assisted by endoscopic guidance. Identification of an ectopic ureter may be assisted by intramural administration of azosulfamid (1.9 mg/kg BW) or intravenous administration of sodium fluorescein (11 mg/kg BW), phenolsulphonphthalein (0.01 mg/kg BW) or indigo carmine (0.25 mg/kg BW) to color the urine being produced, 5–20 minutes before endoscopy; this assists visualization of the urine stream.58

**Cystometry and urethral pressure profile**

Urodynamic tests have been evaluated in the mare that allow comparison of the normal micturition reflex with that of the incontinent patient. Cystometry involves measurement of luminal pressure during inflation of the bladder with measured volumes of 0.9% NaCl or carbon dioxide. The pressure–volume relationship during filling with fluid or gas provides information on bladder capacity, maximal luminal pressure during the detrusor reflex, and stiffness of the bladder wall. The urethral pressure profile involves measurement of pressure along the urethra while withdrawing a fluid- or gas-filled catheter at constant rate. The catheter tip pressure is graphed against distance, and the maximum urethral closure pressure is determined as the maximum urethral pressure minus bladder luminal pressure. The functional urethral length is defined as the length of the urethra in which urethral pressure exceeds bladder luminal pressure.

The test can be performed in restrained mares with or without xylazine sedation (11 mg/kg BW, intravenously), but sedation is recommended. Values for cystometry and urethral pressure profiles in female horses and pony mares are available.59

**Test of uropertoneum and bladder rupture**

Ultrasonographic examination of the abdomen is most useful in detecting the presence of excessive fluid, and this examination frequently allows visualization of the lesion in the bladder or urachus. Further testing is sometimes needed to confirm that the fluid is urine. Generally, in uropertoneum, substantial quantities of fluid can be easily obtained by abdominocentesis. Warming the fluid may facilitate detection of the urine odor, although this is a subjective and poorly sensitive diagnostic test. If there is doubt that the fluid is urine, its creatinine concentration can be compared to the serum creatinine. If creatinine in the fluid is at least twice the serum value, the fluid is confirmed as urine, although ruptured bladder should be suspected whenever the abdominal fluid creatinine concentration exceeds that of serum. In animals with uroabdomen or suspected to have uroabdomen, the administration of 30 mL of sterile 1% ethylene blue into the bladder via a urethral catheter or cystocentesis has been used to confirm the presence of a blue tinge. Absence of a blue color suggests the presence of urethral or renal rupture.

**Radiography**

Radiographic examination has limited value for the diagnosis of urinary tract disease in farm animals but contrast studies may be used to examine the lower urinary tract in neonatal animals. With the widespread availability of ultrasonography and endoscopy, the indications for radiography have become limited. A positive contrast urethrogram was of value in diagnosing urethral recess dilatation in a bull calf,59 and intravenous urography was successful in diagnosing a dilated ureter in a 4-month-old heifer calf.59 Historically, excretory urography, positive contrast cystography and urethrogram have been used, particularly in foals, but these tests are expensive, not widely available and time-consuming. Radiography is currently being performed on animals with equivocal results using other cheaper, faster and more widely available tests.

---

**Principles of treatment of urinary tract disease**

**Fluid and electrolytes**

Treatment of acute renal failure in all species is aimed at removing the primary cause and restoring normal fluid balance by correcting dehydration, acid–base disorders, and electrolyte abnormalities. The prognosis for acute renal failure will depend on the initiating cause and severity of the lesion. If the acute disease process can be stopped the animal may be able to survive on its remaining functional renal tissue. When toxic nephrosis is suspected, an attempt should be made to identify and remove the initiating cause or to move the animal from the suspect environment.

Ruminants with chronic renal failure typically have mild to marked hypoponatremia and hypochloremia; the serum calcium and potassium concentrations may be decreased because of inappetence, serum magnesium concentration may be normal or increased, and serum phosphate concentration may be normal or increased, because urine provides a route of excretion of magnesium and phosphorus. The acid–base status is characterized by metabolic acidosis in severely affected cases to metabolic alkalosis in mildly affected cases. Ruminants with acute renal failure have similar clinicopathological changes, although the serum phosphorus concentration is usually markedly elevated in acute renal failure because many cases are initiated by decreased renal blood flow.

Horses with acute or chronic renal failure have similar electrolyte changes to those in ruminants, with the marked difference being the presence of hypercalcemia and hypophosphatemia in some horses. Hypercalcemia in horses with renal disease is suspected to be due to the relatively greater efficiency of intestinal calcium absorption in the horse, with urine being the predominant route of excretion. Decreases in the function of nephrons in the horse will therefore decrease the urinary loss of calcium and result in hypercalcemia. The hypercalcemia is marked and is thought to result directly in hypophosphatemia in horses with renal failure.

Balanced electrolyte solutions or normal saline supplemented with potassium and calcium can be used to correct fluid and electrolyte deficits. The required volume of replacement fluid can be determined on the basis of clinical signs as outlined in Chapter 2. As the fluid deficit is corrected, the patient should be observed for urination. If anuria or oliguria is present, diuresis will increase the maintenance fluid and electrolyte requirements. The patient should be monitored to prevent overhydration. If the patient has anuria or oliguria after the fluid volume deficit is corrected, a diuretic should be administered to help restore urine flow. Furosemide (1–2 mg/kg BW every 2 h) or mannitol (0.25–2.0 g/kg BW in a 20% solution) may be used, but furosemide is preferred because of its much lower cost and ease of administration. Diuretics should not be used until dehydration has been corrected. After urine flow is restored, the resulting diuresis will increase the maintenance fluid and electrolyte requirements.

**Prognosis for Acute Renal Failure**

- **Horses**: May recover if treated early, but long-term sequelae are common.
- **Cattle**: Prognosis depends on the underlying cause, with cases of nephrosis having a better outcome.
- **Lambs**: Prognosis is guarded, with mortality rates up to 50%.
- **Other Species**: Prognosis varies depending on the species and underlying cause.
fluid requirement. B vitamins should be frequently administered because their rate of loss in the urine is anticipated to be higher than normal in animals with renal failure. Animals nonresponsive to fluid loading and diuretics could be administered low-dose (renal dose) dopamine as a continuous intravenous infusion (2–5 μg/kg BW/min) with dopamine being diluted in 0.9% NaCl, 5% dextrose or lactated Ringer's solution. Dopamine is an α1, β1, β2, DA1, and DA2 agonist and therefore has a complex pharmacodynamic profile that is dependent upon species, organ, and cardiovascular status. Dopamine is theoretically the preferred pharmacological agent to selectively increase renal blood flow and therefore glomerular filtration rate in animals with renal failure, although low-dose dopamine infusion does not alter creatinine clearance (an index of glomerular filtration rate) in healthy adult horses and has not been shown to be of benefit in treating renal failure in humans. At low doses (<5 μg/kg BW/min) dopamine acts primarily as an inotropic agent and at higher doses primarily as a vasopressor. The mean arterial blood pressure and electrocardiogram should therefore be monitored during dopamine administration to insure that dopamine infusion does not lead to hypertension or clinically significant cardiac arrhythmias. Although there are good theoretical grounds for use of dopamine in animals with renal failure, this is no longer the practice in human medicine because of the lack of efficacy of the drug in preventing or treating acute renal failure. Animals that remain anuric after intravenous fluid administration of furosemide/mannitol and dopamine have a grave prognosis and can only be managed with peritoneal dialysis or hemodialysis.

Continuous-flow peritoneal dialysis has also been used in an adult horse using a similar catheterization technique (24 French de Pezzer catheter) and infusion of 10–15 L of warmed, sterile, acetated Ringer's solution. However, only 26–65% of the infused solution was recovered from the abdomen.

Continuous-flow peritoneal dialysis has been used successfully in an adult horse with azotemia refractory to intravenous fluids, furosemide, dopamine infusion and intermittent-flow peritoneal dialysis. A 28 French indwelling thoracic tube was placed in the ventral abdomen and a 2.2 mm diameter, 15 cm long spiral fenestrated catheter was placed in the left flank via peritoneoscopy to allow for inflow of dialysate. Acetated Ringer's with 1.5% glucose was continuously infused through the catheter in the left flank at approximately 3 L/h, with abdominal fluid being collected into a sterile closed collection system from the catheter in the ventral midline of the abdomen.

Hemodialysis was used successfully to treat a foal with presumed oxytetracycline nephrotoxicosis. Hemodialysis was performed under isoflurane anesthesia after surgical placement of a Teflon/Silastic arteriovenous shunt in the median artery and vein using a dialysis delivery system, a hollow-fiber artificial kidney, and acetate-base dialysate. Anticoagulation during dialysis was accomplished with a loading dose of heparin (100 U/kg BW) and then hourly boluses of 20 U/kg BW to prolong the activated clotting time. Three dialysis treatments, lasting 4–6 hours, were administered over a 4-day period, resulting in a marked reduction in azotemia. Hemodialysis is more efficient than peritoneal dialysis and requires shorter treatment intervals, but does require vascular access and anticoagulation treatment, which may predispose to hypotension.

The treatment of chronic renal failure will depend on the stage of disease and the value of the animal. In chronic failure, therapy is aimed at prolonging life. In food-producing animals, emergency slaughter is not recommended because the carcass is usually unsuitable for human consumption. Animals in chronic failure should have free access to water and salt, unless edema is present. Stressors such as sudden environmental and dietary changes should be avoided. The ration should be high in energy-giving food and properly balanced for protein. Acute renal failure may occur in patients in chronic failure and can be treated like other cases of acute renal failure.

Antimicrobial agents
Selection of antimicrobial agents for the treatment of urinary tract infections should be based on quantitative urine culture of a catheterized urine sample. A clinically relevant bacterial concentration indicative of cystitis or pyelonephritis is 1000 or 40 000 cfu/mL of urine from a catheterized or midstream free-catch sample, respectively.

The ideal antimicrobial for treatment of urinary tract infections should meet several criteria. It should:

- Be active against the causal bacteria
- Be excreted and concentrated in the kidney and urine
- Be active at the pH of urine
- Have low toxicity, particularly nephrotoxicity
- Be easily administered
- Be low in cost
- Have no harmful interactions with other concurrently administered drugs.

Appropriate first-line antimicrobials include penicillin, ampicillin, amoxicillin, ceftiofur, and cefquinome in ruminants and trimethoprim–sulfa and ceftiofur in horses. Antimicrobial therapy for lower urinary tract infections should continue for at least 7 days; for upper urinary tract infections 2–4 weeks of treatment is often necessary. Success of therapy can be evaluated by repeating the urine culture 7–10 days after the last treatment.

Manipulation of urine pH should be considered as part of the treatment of bacterial urinary tract infections. In general, Escherichia coli attach best to urinary epithelial cells at pH 6.0, whereas Corynebacterium renale attaches best in alkaline urine. In other words, when treating an E. coli pyelonephritis or cystitis, the diet should be altered to ensure an alkaline urine pH. Likewise, urine pH should be acidic when treating urinary tract infections due to C. renale.

Diseases of the kidney

GLOMERULONEPHRITIS

Glomerulonephritis can occur as a primary disease or as a component of several body systems, such as equine infectious anemia and chronic swine fever. In primary glomerulonephritis, the disease involves only the kidney, predominantly affecting the glomeruli although the inflammatory process extends to affect the surrounding interstitial tissue and blood vessels. Primary and secondary glomerulonephritis are rare causes of clinical disease in farm animals. The disease is sometimes associated with other chronic, systemic illness such as in cows with Johne's disease, bovine virus diarrhea, or leptospirosis; pigs with hog cholera or African swine fever, and horses with equine infectious anemia. Proliferative glomerulonephritis is reported as an incidental finding in normal sheep, cattle, goats, and pigs. Clinical disease from glomerulonephritis is rare in these species but has been reported in cattle and as a congenital condition in sheep, described below. Proliferative glomerulonephritis can cause chronic renal failure in horses. Glomerulonephritis is present in animals with amyloidosis, which is a generalized deposition of antibody-antigen complexes. Amyloidosis is discussed in detail in Chapter 9.

The immune system plays a major role in the pathogenesis of glomerular lesions. Glomerular injury can be initiated by an immune response whereby antibodies are directed against intrinsic glomerular antigens or by foreign antigens planted in the glomerulus. Alternatively, and more commonly, circulating antigen-antibody complexes may be deposited in the glomerulus. As the complexes accumulate, they stimulate an inflammatory response that damages the glomerular filtration system. Inflammatory damage to the glomerulus alters the selective permeability of the filtration system allowing plasma protein, particularly albumin, to pass into the glomerular filtrate. In horses, the glomerular lesion is thought to be caused by the deposition of circulating antigen-antibody complexes but the origin of these complexes is unknown. Infections with streptococci and equine infectious anemia virus may be involved but are not likely to be involved in all cases.

Dermatitis–nephropathy syndrome is a systemic necrotizing vasculitis and glomerulonephritis syndrome of growing pigs in the UK and Canada. The cause is unknown but an immune-mediated pathogenesis is suspected. Growing pigs are affected with a morbidity ranging from 1–3%. The skin is affected with a papular dermatopathy with a characteristic distribution of bluish red spots at least 1 cm in diameter beginning first in the perineal region and then extending to the pelvic limbs and along the ventral body wall to the neck and ears. In the glomeruli, there are extensive granular complement deposits with scattered immunoglobulins.

Porcine dense deposit disease, porcine membranoproliferative glomerulonephritis type II is a common cause of early loss of piglets in the Norwegian Yorkshire breed. The disease is associated with extensive complement activation due to a deficiency of factor H, a plasma protein that regulates complement. Affected piglets are clinically normal at birth and for the first few weeks of life. Thereafter they become unthrifty and die from renal failure within 72 days of birth. In the kidneys there is extensive glomerular proliferation and marked thickening of the glomerular capillary wall. Large amounts of dense deposits are consistently found within the glomerular basement membrane. This disease is inherited with a simple autosomal recessive pattern and complete penetrance. A pathogenetic mechanism of a defective or missing complement regulation protein is hypothesized. A spontaneous glomerulonephritis of unknown etiology and unrelated to any breed has been recorded in pigs. A necrotizing glomerulonephritis is listed as occurring in pigs fed a waste product from an industrial plant producing a proteolytic enzyme. Glomerulonephritis has also been recorded in pigs in the absence of clinical illness, although an association with the 'thin sow' syndrome is suggested.

In Finnish Landrace lambs less than 4 months of age there is an apparently inherited disease that is remarkably similar to forms of human glomerulonephritis. Affected lambs appear to absorb an agent from colostrum that induces an immunological response, followed by the granular deposition of immune complexes and complement within the glomerular capillary walls; this initiates a fatal mesangiocapillary glomerulitis. Many affected lambs are asymptomatic until found dead. Some have signs of tachycardia, edema of the conjunctiva, nystagmus, walking in circles and convulsions. The kidneys are enlarged and tender. There is severe proteinuria and low plasma albumin. Serum urea concentration is increased (>35 mmol/L) with hyperphosphatemia and hypocalcemia.
At necropsy the kidneys are large and pale and have multifocal pinpoint yellow and red spots throughout the cortex. On histopathological examination there are severe vascular lesions in the choroid plexuses and the lateral ventricles of the brain. The disease is thought to be conditioned in its occurrence by inheritance and to be limited to the Finnish Landrace breed. However, cases have also occurred in crossbred lambs.

Glomerulopathy and peripheral neuropathy in Gelbvieh calves is a familial, and probably heritable, disease causing illness in calves of this breed of less than 13 months of age. The initial physical abnormality is posterior ataxia that progresses to generalized paresis and recumbency. The neurological deficits include loss of conscious proprioception, diminished or absent peripheral reflexes but maintained consciousness. Affected animals continue to eat and drink normally. Serum creatinine and urea concentrations are markedly elevated. Necropsy examination reveals neuropathy, myelopathy, and glomerulopathy. The disease is terminal.

Glomerulonephritis is a common cause of chronic renal failure in horses. Several forms of glomerulonephritis are recognized in horses: membranous glomerulonephritis, post-streptococcal glomerulonephritis, membranoproliferative glomerulonephritis and focal glomerulosclerosis. As discussed above, most are probably immune-mediated and associated with circulating antibody-antigen complexes. Over 80% of horses with equine infectious anemia have glomerular lesions, and viral antigen-antibody complexes are present in the glomerular basement membrane. Purpura hemorrhagica is associated with glomerulonephritis.

DISEASES OF THE KIDNEY

DIFFERENTIAL DIAGNOSIS

Evidence of oliguria and azotemia in the presence of circulatory failure suggests renal ischemia and the possibility of permanent renal damage. It is important to attempt to differentiate the early reversible prerenal stage from the stage when degeneration of renal parenchyma has occurred. When ischemic renal lesions are present, urinalysis may be helpful in diagnosis, particularly if urine is not appropriately concentrated in a dehydrated patient. After irreversible ischemic changes have occurred it is impossible to differentiate clinically between ischemia and other primary renal diseases such as glomerulonephritis and toxic nephrosis. History and clinical signs of chronic disease will help determine if the acute syndrome is superimposed on chronic renal disease.

TOXIC NEPHROSIS

The kidneys are particularly vulnerable to endogenous and exogenous toxins because they receive a large proportion of the total cardiac output and because substances are concentrated in the kidney for excretion.

ETIOLOGY

Most cases of nephrosis are caused by the direct action of toxins but hemodynamic changes may contribute to the pathogenesis.

Toxins
- Metals – mercury, arsenic, cadmium, selenium, organic copper compounds; nephrosis can be reproduced experimentally in horses by the oral administration of potassium dichromate and mercuric chloride, including topical blistering agents containing mercuric chloride.
- Antimicrobials such as aminoglycosides, and overdosing with neomycin and gentamicin in treatment of calves. Treatment with tetracycline preparations accidentally contaminated by tetracycline degradation compounds and repeated daily dosing with long-acting oxytetracycline preparations may induce toxicity. Treatment with sulfonamides.
- Horses treated with vitamin K₃ (menadione sodium bisulfite) administered by intramuscular or intravenous injection.
- Horses treated with vitamin D₂ (ergocalciferol) and cholecalciferol (D₃).
- Treatment of horses with nonsteroidal anti-inflammatory drugs (NSAIDs), including phenylbutazone and flunixin meglumine. Dose rates of more than 8.8 mg/kg BW of phenylbutazone per day for 4 days are likely to cause nephrosis. Doses of 4.4 mg/kg BW are considered to be safe but the toxicity is enhanced by water deprivation. More commonly, NSAID toxicity occurs as interstitial nephritis and renal crest necrosis. The usual presentation of NSAID toxicosis in horses is gastrointestinal ulceration, including right dorsal colitis.
- Benzimidazole compounds used as anthelmintics; only some of them including thiabendazole.
- Monensin in ruminants.
- Low-level aldrin poisoning in goats.
- Highly chlorinated naphthalenes.
- Oxalate in plants, listed under the heading of oxalate poisoning.
- Oxalate in fungi, e.g. *Penicillium* spp. and mushrooms.
- Oxalate in ethylene glycol or ascorbic acid, which is a metabolic precursor to oxalate.
- Primary hyperoxaluria due to inherited metabolic defect in beef master calves.
- Tannins in the foliage of oak trees and acorns.
- Unidentified toxin in *Amaranthus retroflexus* in pigs and cattle in *Narthecium asiaticum* fed to cattle and *Isotropis forrestii* in ruminants.
- Mycotoxins: ochratoxins and citrins, fumonisins in ruminants.
- Ingestion of *Lophyrotoma interrupta* (savfly) larvae by cattle.
- Cantharidin in horses following ingestion of dead blister beetles in alfalfa hay and hay products.
- Most nonspecific endogenous or exogenous toxemias cause some degree of temporary nephrosis.

PATHOGENESIS

In acute nephrosis there is obstruction to the flow of glomerular filtrate through the tubules as a result of interstitial edema and intraluminal casts. If there is sufficient tubular damage, there may be back leakage of glomerular filtrate into the interstitium. There may also be a direct toxic effect on glomeruli, which decreases glomerular filtration. The combined effect is oliguria and uremia. In subacute cases, impaired tubular resorption of solutes and fluids may lead to polyuria.

NECROPSY FINDINGS

In acute cases the kidney is swollen and wet on the cut surface and edema, especially of perirenal tissues, may be apparent. Histologically there is necrosis and desquamation of tubular epithelium, and hyaline casts are present in the dilated tubules. In phenylbutazone poisoning the renal lesion is specifically a renal medullary necrosis. There may also be ulcers in all or any part of the alimentary tract from the mouth to the colon if phenylbutazone was administered orally.

TREATMENT

Treatment should be directed at general supportive care for acute renal disease as outlined above. If the toxin can be identified, it should be removed. Treatment for specific toxins may be available, as described elsewhere in the text. Hemodialysis was used successfully to treat a foal with presumed oxytetracycline nephrotoxicosis.

CLINICAL FINDINGS

Clinical signs may not be referable to the urinary system. In peracute cases, such as those caused by vitamin K₃ administered by injection, there may be colic and stranguria. In acute nephrosis there is oliguria and proteinuria with clinical signs of uremia in the terminal stages. These signs include depression, dehydration, anorexia, hypothermia, a slow or an elevated heart rate, and weak pulse. Diarrhea may be present that is sufficiently intense to cause severe clinical dehydration. In cattle there is a continuous mild hypocalcaemia with signs reminiscent of that disease, which responds, in a limited way, to treatment with calcium. Cattle with advanced and severe nephrosis may exhibit a bleeding diathesis. Polyuria is present in chronic cases.

Many systemic diseases such as septicaemia cause temporary tubular nephrosis. The degree of renal epithelial loss is not sufficient to cause complete renal failure and, provided the degree of renal damage is small, complete function is regained.
Clinical differentiation from acute glomerulonephritis is difficult but clinical signs of involvement of other organs in the toxic process may be present:

- A combination of polyuria and glycosuria is an uncommon finding in large animals and is usually caused by nephrosis.
- Diabetes mellitus is rare in horses and extremely rare in ruminants.
- Cushing’s syndrome (chronic hyperadrenocorticism pituitary pars intermedia dysfunction) is more common in horses but this includes characteristic signs of polyuria, glycosuria, debilitation, hirsutism, polyphagia, and hyperglossia.
- Diarrhea in terminal stages of uremia in a horse can be confused with the other causes of acute diarrhea. It requires a blood urea and creatinine estimation and a urinalysis for differentiation.

REVIEW LITERATURE

RENAI TubULAR ACIDOSIS

Renal tubular acidosis (RTA) is a rare disease of large animals that is characterized by normal glomerular function but abnormal tubular function. RTA should be suspected whenever there is a profound strong ion acidosis due to hyperchloremia (normal anion gap metabolic acidosis), accompanied by an alkaline urine pH (typically > 8.0) and increased fractional clearance of sodium.

A practical diagnostic test for distal RTA involves examining the ability of the distal convoluted tubules to excrete hydrogen ions by the oral administration of ammonium chloride. The initiating cause of renal disease is usually not evident but most cases are believed to begin with acute tubular nephrosis. Horses with chronic interstitial nephritis have the clinical syndrome of chronic renal failure with uremia.

REFERENCES

EMBOLIC NEPHRITIS

Embolic suppurative nephritis or renal abscesses may occur if the primary focus is extrarenal. The condition is not common but is important because of the resultant destruction of nephrons that occurs. The kidney is an important site for bacteria in other species, particularly cattle, but renal disease is not a common clinical problem in carrier animals.

Chronic interstitial fibrosis is a common postmortem finding in horses suffering from chronic renal failure. This is believed to represent an end-stage condition rather than primary interstitial disease. The initiating cause of the renal disease is usually not evident but most cases are believed to begin with acute tubular nephrosis. Horses with chronic interstitial nephritis have the clinical syndrome of chronic renal failure with uremia.

REFERENCES

INTERSTITIAL NEPHRITIS

Interstitial nephritis is rarely recognized as a cause of clinical disease in farm animals although it is a frequent postmortem finding in some species. Interstitial nephritis may be diffuse or have a focal distribution. In calves, focal interstitial nephritis (white-spotted kidney) is a common incidental finding at necropsy but does not present as a clinical urinary tract disease. Focal interstitial nephritis of cattle is not associated with leptospirosis or active bacterial infection. In pigs, diffuse interstitial nephritis is observed following infection by Leptospira sp. and is important clinically because of the resultant destruction of nephrons that occurs. The kidney is an important reservoir for Leptospira spp. in other species, particularly cattle, but renal disease is not a common clinical problem in carrier animals.

Chronic interstitial fibrosis is a common postmortem finding in horses suffering from chronic renal failure. This is believed to represent an end-stage condition rather than primary interstitial disease. The initiating cause of the renal disease is usually not evident but most cases are believed to begin with acute tubular nephrosis. Horses with chronic interstitial nephritis have the clinical syndrome of chronic renal failure with uremia.

REFERENCES
PATHOGENESIS
Bacterial emboli localize in renal tissue and cause the development of focal supplicative lesions. Emboli can block larger vessels and cause infarction of portions of kidney, the size varying with the caliber of the occluded vessel. Infarcts are not usually so large that the residual renal tissue cannot compensate fully and they usually cause no clinical signs. If the urine is checked repeatedly, the sudden appearance of proteinuria, casts, and microscopic hematuria, without other signs of renal disease, suggests the occurrence of a renal infarct. The gradual enlargement of focal embolic lesions leads to the development of toxemia and gradual loss of renal function. Clinical signs usually develop only when multiple emboli destroy much of the renal parenchyma, or when there is one or more large infected infarcts.

CLINICAL FINDINGS
Usually there is insufficient renal damage to cause signs of renal disease. Signs of toxemia and the primary disease are usually present. The kidney may be enlarged on rectal examination. Repeated showers of emboli or gradual spread from several large, supplicative infarcts may cause fatal uremia. Spread to the renal pelvis may cause signs similar to pyelonephritis. Large infarcts may cause bouts of transient abdominal pain.

CLINICAL PATHOLOGY
Hematuria and pyuria are present but microscopic examination may be necessary to detect these abnormalities when the lesions are minor. Proteinuria is present but is also normally present in neonatal animals in the first 30–40 hours of life. Culture of urine at the time when proteinuria occurs may reveal the identity of the bacteria infecting the embolus. Hematology usually reveals evidence of an acute or chronic inflammatory process.

NECROPSY FINDINGS
In animals that die of intercurrent disease the early lesions are seen as small gray spots in the cortex. In later stages these lesions may have developed into large abscesses, which may be confluent and in some cases extend into the pelvis. Fibrous tissue may surround long-standing lesions and healed lesions consist of areas of scar tissue in the cortex. These areas have depressed surfaces and indicate that destruction of cortical tissue has occurred. Extensive scarring may cause an obvious irregular reduction in the size of the kidney.

TREATMENT
General information on treatment of urinary tract infections is presented in the section on treatment of urinary tract diseases. Antimicrobials should be selected on the basis of quantitative urine culture and susceptibility testing. In treating septicemic neonatal animals, particular care must be taken to avoid the use of potentially nephrotoxic drugs. Antibiotic treatment should be continued for a fairly lengthy period (7–14 d). In embolic nephritis, the primary disease must be controlled as well as the renal disease to prevent recurrence of the embolic lesions. In neonatal animals this may involve treatment for septic shock. The urine culture should be repeated at intervals after treatment is completed to insure that the infection has been completely controlled.

DIFFERENTIAL DIAGNOSIS
<table>
<thead>
<tr>
<th>Differential Diagnosis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pyelonephritis is usually characterized by acute or chronic inflammatory process.</td>
</tr>
</tbody>
</table>

PYELONEPHRITIS
Pyelonephritis usually develops by ascending infection from the lower urinary tract. Clinically it is characterized by pyuria, hematuria, cystitis, ureteritis, and suppurative nephritis.

ETOLOGY
Pyelonephritis may develop in a number of ways:
- Secondary to bacterial infections of the lower urinary tract
- Spread from embolic nephritis of hematological origin such as septicemia in cattle associated with *Pseudomonas aeruginosa*
- Specific pyelonephritides associated with *C. renale*, *Corynebacterium pilosum* (formerly *C. renale* type 2) and *Corynebacterium cystitidis* (formerly *C. renale* type 3) in cattle and *Corynebacterium suis* in pigs
- Secondary to anatomical abnormalities of the kidneys or distal structures permitted ascending infection of the kidney
- In association with nephroliths, although whether the nephrolith or the pyelonephritis occurred first is uncertain.

PATHOGENESIS
Pyelonephritis develops when bacteria from the lower urinary tract ascend the ureters and become established in the renal pelvis and medulla. Bacteria are assisted in ascending the ureters by urinary stasis or reflux of urine from the bladder. Ureteral obstruction may occur as a result of blocking of the ureters by inflammatory swelling or debris, by pressure from the uterus in pregnant females and by obstrusive urolithiasis. Initially the renal pelvis and medulla are affected because they are relatively more hypoxic and localized tissue hypertonicity depresses the phagocytic function of leukocytes. Infection in advanced cases may extend to the cortex.

Pyelonephritis causes systemic signs of toxemia and fever and, if renal involvement is bilateral and sufficiently extensive, uremia develops. Pyelonephritis is always accompanied by pyuria and hematuria because of the inflammatory lesions of the ureters and bladder.

Pyelonephritis in cattle due to *C. renale* used to be very common but clinical disease has decreased markedly, with the majority of pyelonephritis cases in cattle now being due to *E. coli*. The reason for the decrease in *C. renale* isolation from clinical cases is unclear but is probably related to a change in diet towards concentrates with an associated decrease in urine pH; other potential reasons could be the widespread use of beta-lactam antibiotics and the marked decrease in urethral catheterization in order to obtain a urine sample in cows suspected to be ketotic. *C. renale* attaches most efficiently to well-differentiated epithelial cells (transitional epithelium cells), with poor attachment at pH less than 6.8, a rapid increase in adhesion from 6.8 to 7.6, and a high rate of attachment at pH above 7.6.

*C. renale* used to be typed as 1, 2, and 3, but the latter two have been renamed *C. pilosum* (formerly *C. renale* type 2) and *C. cystitidis* (formerly *C. renale* type 3), with apparent type differences in their preferred colonization site in the vagina and urethra. Uropathogenic strains of *E. coli* also attach to epithelial cells by a type 1 pili, with the optimal pH for attachment of 6.0. Attachment of bacterial to urinary epithelium appears to be an important virulence attribute.

Transmission of *C. suis* in pigs may occur after mating with infected boars, because many boars carry *C. suis* in their preputial or buccal sapid fluid. Field observations
suggest that slight trauma at breeding, especially in small gilts, may be an important factor in transmission.4

CLINICAL FINDINGS
The clinical findings in pyelonephritis vary between species. In sows there may be an initial period during which a vaginal discharge is noted but most affected animals die without premonitory illness. Characteristically, affected pigs will lose weight and eventually become emaciated.5 The disease in cattle is described in detail in the section on bovine pyelonephritis.

The disease in horses is often chronic, although acute disease occurs. Gross hemorrhage is recognized in some horses with pyelonephritis, although this is not a common finding.5 Ultrasonographic examination of the kidneys can confirm the diagnosis, based on the presence of abnormally shaped kidneys with loss of the corticomedullary gradient, hypo- or hyperechoic abnormalities in the renal cortex, and increased echogenicity. These findings should prompt examination of the urine for leukocytes, casts, protein, and bacteria.

CLINICAL PATHOLOGY
Erythrocytes, leukocytes, and cell debris are present in the urine on microscopic examination and may be grossly evident in severe cases, particularly in horses.5 Quantitative urine culture is necessary to determine the causative bacteria.

NECROPSY FINDINGS
The kidney is usually enlarged and lesions in the parenchyma are in varying stages of development. Characteristic lesions are necrosis and ulceration of the pelvis and papillae. The pelvis is usually dilated and contains clots of pus and turbid urine. Streaks of gray, necrotic material radiate out through the medulla and may extend to the cortex. Affected areas of parenchyma are necrotic and may be separated by apparently normal tissue. Healed lesions appear as contracted scar tissue. Infarction of lobules may also be present, especially in cattle. Histologically the lesions are similar to those of emboilic nephritis except that there is extensive necrosis of the apices of the papillae. Necrotic, suppurative lesions are usually present in the bladder and ureters.

TREATMENT
General principles of treatment of urinary tract infections are presented above in the section on treatment of urinary tract disease. A specific treatment for severe asymmetric pyelonephritis is unilateral nephrectomy, but this should only be done in nonazotemic animals. An over-looked component of treatment is alteration in urinary pH, which will affect the ability of the bacteria to attach to epi-

DIFFERENTIAL DIAGNOSIS
The presence of pus and blood in the urine may suggest cystitis or embolic nephritis as well as pyelonephritis. It may be difficult to distinguish between these diseases but renal enlargement or pain on rectal palpation of the kidney indicates renal involvement. Ultrasonographic changes associated with pyelonephritis include a dilated renal collecting system, renal or ureteral calculi, increased echogenicity, loss of corticomedullary echogenicity and subjective enlargement of the kidney with acute disease or a small irregular kidney with chronic disease.6,7 Parenchymal hyperechogenicity can be caused by tubular degeneration and replacement fibrosis.

RENFAL NEOPLASMS
Primary tumors of the kidney are uncommon. Carcinomas occur in cattle and horses and nephroblastomas occur in pigs. Enlargement of the kidney is the characteristic sign; in cattle and horses neoplasm should be considered in the differential diagnosis of renal enlargement. In pigs, nephroblastomas may reach such a tremendous size that they can cause visible abdominal enlargement. Renal adenocarcinomas are very slow-growing but are not usually diagnosed until the disease is well advanced. The gross and histological descriptions of a series of primary renal cell tumors in slaughter cattle have been recorded.1 In horses, the most common signs are weight loss, reduced appetite and intermittent bouts of abdominal pain.2,3 Some affected horses have massive ascites, hemoperitoneum, or hematuria.2,3 Metastasis of the tumor to the axial skeleton can result in lameness, which can be the clinical abnormality that is recognized first.4,5 The tumor can also metastasize to the lungs and mouth.5,6 Masses on the left kidney of horses are usually readily palpable on rectal examination.7 Horses with renal carcinoma can have clinically apparent periods of hypoglycemia.7 Hypoglycemia is confirmed by measurement of serum glucose concentration and is attributable to production of insulin-like growth factor by the neoplastic tissue.8 Ultrasonographic examination of the kidney, and renal biopsy, confirm the diagnosis.

Metastatic neoplasms occur fairly commonly in the kidney, particularly in enzootic bovine leukosis, but they do not cause clinical renal disease. Tumor masses may be palpable as discrete enlargements in the kidneys of cattle or may involve the kidney diffusely, causing generalized enlargement of the kidney.

Diseases of the bladder, ureters and urethra

CYSTITIS

Inflammation of the bladder is usually associated with bacterial infection and is characterized clinically by frequent, painful urination (pollakiuria and dysuria) and the presence of blood (hematuria), inflammatory cells and bacteria in the urine.

ETIOLOGY

Cystitis occurs sporadically as a result of the introduction of infection into the bladder when trauma to the bladder has occurred or when there is stagnation of the urine. In farm animals the common associations are:

- Cystic calculus
- Difficult parturition
- Contaminated catheterization
- Late pregnancy
- As a sequel to paralysis of the bladder. A special case of bladder paralysis occurs in horses grazing sudax or Sudan grass and in horses with equine herpesvirus myoencephalopathy.

In the above cases, the bacterial population is usually mixed but predominantly *E. coli*. There is also the accompanying of specific pyelonephritides in cattle and pigs, associated with *C. renale* and *Eubacterium suis*, respectively. Many sporadic cases also occur in pigs, especially after farrowing. Common isolates from these are *E. coli*, *Streptococcus*, and *Pseudomonas* spp. *Corynebacterium matruchotii* causes encrusted cystitis in horses. Enzootic hematuria of cattle resembles but is not a cystitis.

PATHOGENESIS

Bacteria frequently gain entrance to the bladder but are usually removed by the flushing action of voided urine before they invade the mucosa. Mucosal injury facilitates invasion but stagnation of urine is the most important predisposing cause. Bacteria usually enter the bladder by ascending the urethra but descending infection from enteral nephritis may also occur.

CLINICAL FINDINGS

The urethritis that usually accompanies cystitis causes painful sensations and the desire to urinate. Urination occurs frequently and is accompanied by pain and sometimes grunting; the animal remains in the urination posture for some minutes after the flow has ceased, often manifesting additional expulsive efforts. The volume of urine passed on each occasion is usually small. In very acute cases there may be moderate abdominal pain, as evidenced by treading with the hindfeet, kicking at the belly and swishing with the tail, and a moderate febrile reaction. Acute retention may develop if the urethra becomes blocked with pus or blood, but this is unusual.

Chronic cases show a similar syndrome but the signs are less marked. Frequent urination and small volume are the characteristic signs. In chronic cases, the bladder wall may feel thickened on rectal examination and, in horses, a calculus may be present. In acute cases no palpable abnormality may be detected but pain may be evidenced. Endoscopic examination of the bladder of affected horses reveals widespread inflammation of the cystic mucosa and occasionally the presence of a cystic calculus.

CLINICAL PATHOLOGY

Blood and pus in the urine is typical of acute cases and the urine may have a strong ammonia odor. In less severe cases the urine may be only turbid and in chronic cases there may be no abnormality on gross inspection. Microscopic examination of urine sediment will reveal erythrocytes, leukocytes, and desquamated epithelial cells. Quantitative bacterial culture is necessary to confirm the diagnosis and to guide treatment selection.

NECROPSY FINDINGS

Acute cystitis is manifested by hyperemia, hemorrhage and edema of the mucosa. The urine is cloudy and contains mucus. In subacute and chronic cases the wall is grossly thickened and the mucosal surface is rough and coarsely granular. Highly vascular papillary projections may have eroded, causing the urine to be bloodstained or contain large clots of blood. In the cystitis associated with Sudan grass, soft masses of calcium carbonate may accumulate in the bladder and the vaginal wall may be inflamed and coated with the same material.

TREATMENT

Antimicrobial agents are indicated to control the infection and determination of the antimicrobial susceptibility of the causative bacteria is essential. Relapses are common unless treatment is continued for a minimum of 7 and preferably 14 days. Repeated bacterial culture of urine at least 7-10 days after completion of treatment should be used to assess the success of therapy. Recurrence of the infection is usually due to failure to eliminate foci of infection in the accessory glands and in the bladder wall.

The prognosis in chronic cases is poor because of the difficulty of completely eradicating the infection and the common secondary involvement of the kidney. Free access to water should be permitted at all times to insure a free flow of urine.

PARALYSIS OF THE BLADDER

Paralysis of the bladder is uncommon in large animals. Paralysis usually occurs as a result of neurological diseases affecting the lumbar spinal cord such as equine herpes myelopathy and cauda equina syndrome, and particularly ascending spinal meningitis in lambs after tail docking. In all species, compression of the lumbar spinal cord by neoplasia (lymphosarcoma, melanoma) or infected tissue (vertebral osteomyelitis) can cause paralysis of the bladder. Excessive tension on the tail, such as with tail ropes or use of the tail for restraint in cattle, can injure the cauda equina and cause bladder paralysis. In horses, spinal cord degeneration following consumption of sorghum can lead to bladder paralysis and posterior
Bladder rupture leads to gradual development of ascites from uroperitoneum, mural stasis, constipation, and depression. In cattle, uremia may take 1-2 weeks to develop to the point where euthanasia is necessary. The degree of uremia between individual patients can be highly variable. With therapy, the survival rate of steers in one study was 49%. The best predictor of survival among clinical pathology tests was the serum phosphate concentration: all animals with levels greater than 9.0 mg/dL (2.9 mmol/L) died. In mature horses, clinical signs of depression, anorexia, colic, abdominal distension, and uremia develop within 1-2 days following rupture.

In cases of ascites or when urinary tract obstruction is evident, it is important in considering treatment and prognosis to determine whether the bladder has ruptured. The urea and creatinine concentrations in plasma can be compared to the values in the peritoneal fluid. The ratio of urea in peritoneal fluid to that in serum is a good guide in the early stages, but after 40 hours the ratio of the peritoneal to serum creatinine greater than 2:1 is diagnostic of uroperitoneum. Treatment is surgical with a goal of bladder repair. To avoid the costs of laparotomy in feedlot animals, a urethrostomy is created or an indwelling catheter is placed and the rupture is allowed to repair itself.

UROPERITONEUM IN FOALS (UROABDOMEN)

ETIOLOGY
Uroperitoneum, the accumulation of urine in the peritoneal cavity, occurs in foals as a result of a variety of situations:
- Congenital (i.e. present at birth) rupture of the bladder
- Bladder rupture associated with sepsis
- Urethral rupture, often secondary to sepsis
- Avulsion of the bladder from its urachal attachment, presumably as a result of trauma or strenuous exercise
- Rarely, as embryological failure of the halves of the bladder to unite (schistocystitis)
- Ureteral defects.

The etiology of congenital rupture is unclear, but its association with birth, markedly greater prevalence in colts, and

Rupture of the bladder (Uroperitoneum)

This occurs most commonly in castrated male ruminants as a sequel to obstruction of the urethra by calculi. Rare cases are recorded in cows as a sequel to a difficult parturition1-3 and in mares after normal parturition, 4 possibly because of compression of a full bladder during foaling. In cattle, abnormal fetal position during prolonged dystocia is suspected to obstruct the urethra and distend the bladder. Subsequent manipulation within the pelvic canal during correction of the dystocia is suspected to lead to rupture of a distended bladder. Uroperitoneum in foals is discussed in the next section. After the bladder ruptures, uroperitoneum results in a series of abnormalities that arise from failure of the excretory process combined with solute and fluid redistribution between the peritoneal fluid and extracellular fluid. The peritoneal membrane serves as a semipermeable membrane through which low-molecular-weight solutes readily pass. High-molecular-weight compounds also diffuse across the peritoneal membrane but at a much slower rate. Urine is usually hypertonic especially in animals whose water intake is decreased by uremia. Osmotic pressure from hypertonic urine promotes movement of extracellular water into the peritoneal cavity. This movement, combined with reduced intake, results in clinical dehydration. Urine usually has a lower concentration of sodium and chloride and higher concentrations of urea, creatinine, potassium, and phosphate than plasma. Diffusion along these concentration gradients across the peritoneal membrane results in a general pattern of azotemia with hypernatremia, hypochloremia, hyperkalemia, and hypophosphatemia.5 There are minor differences between species in these general biochemical changes. In particular, the blood concentration of urea rises much more slowly in ruminants than in horses, and hyperkalemia is not as common in ruminants as in horses because excessive potassium can be excreted in the saliva and therefore eliminated in the feces.

Bladder wall thickness. No evidence of neurological injury was present, and it is likely that urine retention was secondary to severe cystitis and swelling of the bladder wall that prevented normal urination.

PART 1 GENERAL MEDICINE Chapter 11: Diseases of the urinary system
the traumatic nature of the lesion suggests that it occurs during birth as a result of compression of a distended bladder. Intra-abdominal pressures of the mare during parturition are large, and these compressive forces are experienced by the foal during phase 2 of parturition. Compression of a distended bladder can cause rupture. The greater prevalence in colts is speculated to be a result of the greater resistance to bladder emptying conferred by the longer urethra of male foals.

Rupture of the bladder occurs as a distinct entity in septic foals. The underlying reason for bladder rupture is unclear but is usually related to infection, inflammation and necrosis of the lower urinary tract. This cause of uroperitoneum in foals is increasingly recognized as the most common, especially amongst hospitalized foals.

Rupture of the urachus occurs in septic foals. It is probably of similar etiology to rupture of the bladder in septic foals. The urachus of affected foals almost always has infection, inflammation and necrosis evident on histological examination.

Avulsion of the bladder from its urachal attachments is presumed to occur as a result of trauma, such as might occur with vigorous exercise. The possibility also exists that there is an underlying defect in affected foals, such as urachitis or omphalitis.

Embryological failure of the halves of the bladder to unite during organogenesis has been reported anecdotally and in case reports, although adequate documentation of its occurrence is lacking. This defect would be a true congenital anomaly, arising during gestation.

Ureteral defects are an uncommon cause of uroperitoneum in foals. The defects appear to be congenital and more common in fillies. Both ureters can be affected.

The relative frequency of these diseases is that approximately 20% of foals with uroperitoneum do so because of urachal rupture, approximately 30% because of rupture of the dorsal bladder wall, 18% because of rupture of the ventral bladder wall and the remainder because of multiple defects involving combinations of the urachus, dorsal and ventral bladder.

Uroperitoneum also occurs in calves as a consequence of umbilical infection.

**EPIDEMIOLOGY**

The epidemiology of uroperitoneum is not well documented. The incidence in foals appears to be approximately 0.2%, although this estimate is based on a study conducted 50 years ago. The prevalence in hospitalized foals is 2.5%. Male foals are at greater risk than are females for congenital rupture, more than 80% of foals with this disease being colts. In contrast, there is no sex predilection for development of uroperitoneum in foals with sepsis. The age at diagnosis ranges from 2 to more than 60 days, with most cases recognized within the first 2 weeks of life. The average age at diagnosis is approximately 4-5 days, although the age at presentation depends on the underlying cause. Foals with congenital rupture of the bladder or ureteral defects are usually recognized at about 3-5 days of age, while foals with uroperitoneum secondary to sepsis are usually older (5-9 days of age, but up to 60 days).

The prognosis for survival for foals with uroperitoneum depends on the underlying cause and availability of appropriate treatment. Foals with congenital rupture of the bladder that are recognized and treated in a timely fashion have an excellent prognosis (> 80%) for survival, whereas those with uroperitoneum secondary to sepsis have a more guarded prognosis (50-60%) because of the sepsis.

**PATHOPHYSIOLOGY**

The pathophysiology of uroperitoneum is that of postrenal azotemia. Regardless of the underlying cause of the uroperitoneum, accumulation of urine within the peritoneal cavity results in substantial electrolyte, acid-base and cardiovascular effects in affected foals. The basic principle is that affected foals are unable to excrete metabolic waste products that are normally excreted in the urine, and are unable to maintain water and electrolyte balance. Young foals derive almost all of their nutritional needs, including water, from mare's milk. Mare's milk has a low sodium concentration (approximately 12 mEq/L) and a high potassium concentration (25 mEq/L) compared to serum, and a dry matter content of 11%. Therefore, foals ingest a diet that contains a large quantity of water and potassium but little sodium. Consequently, the urine of foals contains little sodium (7 mmol/L) and has a low osmolality (100 mosmol/kg). Leakage of urine into the peritoneum, a semi-permeable membrane, results in considerable fluid and electrolyte shifts. Partial equilibration of water and electrolytes across the peritoneal membrane results from diffusion of water from the peritoneum with resultant dilution of serum and reductions in serum sodium and chloride concentrations. The low concentration of sodium in uninfurinuous peritoneal fluid favors diffusion of sodium from the blood into the peritoneal fluid, with the result that there is a reduction in intravascular sodium content and a consequent reduction in effective circulating volume. Excretion of relatively large quantities of potassium in urine and accumulation of potassium-rich fluid in the peritoneum allows diffusion of potassium into the blood and an increase in plasma potassium concentration. The peritoneal membrane is permeable to creatinine and urea, as evidenced by the efficacy of peritoneal lavage in treatment of renal failure in a variety of species, including horses. Consequently, serum creatinine and urea concentrations are higher in foals with uroperitoneum than in unaffected foals. However, equilibration of concentrations of these compounds is not complete and peritoneal fluid concentrations of urea, creatinine, and potassium are higher than those in serum.

Foals with uroperitoneum have compromised circulatory function because of reduced effective circulating plasma (blood) volume, despite having an increased total body water content. Circulatory function is further impaired by a combination of the hyperkalemia, abdominal distension and accumulation of fluid in the pleural space, with the result that foals with uroperitoneum can have signs of mild to moderate circulatory compromise.

Hyperkalemia and acidosis associated with uroperitoneum predispose affected foals to development of malignant cardiac rhythm, including ventricular tachycardia and fibrillation. This abnormal cardiac rhythm is a common cause of death of affected foals.

**CLINICAL SIGNS**

Clinical signs in foals with uroperitoneum depend in part on the underlying disease. Foals with congenital rupture or mild sepsis have progressive signs of lethargy, decreased appetite, mild abdominal discomfort, and abdominal distension. These signs usually first become apparent at 2-4 days of age. These foals do not typically have a fever. As the disease progresses and the amount of urine accumulated in the peritoneum increases, foals have progressive distension of the abdomen and make frequent attempts to urinate. Foals attempting to urinate ventroflex the back (mild lordosis) and have a wide-based stance, in contrast with foals with tenesmus, which characteristically have a narrow-based stance (all four limbs being under the body) and arch their back. Affected foals sometimes produce small quantities of urine, but usually there is lack of urination. Abdominal distension is most apparent when the foal is standing. In moderate to severe cases there is a readily appreciable fluid wave on ballotment of the abdomen. As abdominal distension increases the foal's tidal
volume is impaired and breathing becomes rapid and shallow. The extremities become cool as cardiovascular function is impaired.

Ventral edema and preputial swelling occur in some foals. Foals with a urachal rupture close to or within the abdominal wall or in the subcutaneous tissues will have subcutaneous accumulation of urine (which can be mistaken for ventral edema).

Foals with uroperitoneum secondary to sepsis usually have signs of sepsis as the initial and predominant sign of disease. These signs can range from mild fever and enlargement of the umbilical structures to septic shock and its attendant abnormalities. Initial signs of uroperitoneum in these foals are easily overlooked. As the disease develops these foals have progressive abdominal distension. Signs of cardiovascular dysfunction can be incorrectly attributed to worsening of sepsis. It is important when treating septic foals to maintain a high index of suspicion and constant vigilance for development of uroperitoneum.

Infusion of contrast agents, such as methylene blue or fluorescein, into the bladder with subsequent detection of these compounds in the peritoneal fluid has been used to diagnose uroperitoneum. However, use of this method of diagnosis is now obsolete except in those instances in which ultrasonographic examination of the foal is not possible.

Imaging

Ultrasonographic examination of the abdomen of foals has simplified detection of uroperitoneum in foals and is the preferred imaging modality for detection of excessive peritoneal fluid in foals. The ultrasound examination is best performed with a 5 MHz sector scanner, with more detailed examination of the umbilical structures performed using a 7 MHz linear or sector scanner. However, diagnosis of the presence of excessive peritoneal fluid can be achieved using a 7 MHz linear scanner, such as is routinely used for examination of the mare reproductive tract. The examination is performed transcervically.

Ultrasonography reveals the presence of an excessive amount of fluid that is minimally echogenic. Intestines, mesentery, and omentum are readily visualized floating in this fluid. The presence of a large quantity of minimally echogenic fluid in the peritoneum of foals is very specific (effectively 100%) for uroperitoneum. The procedure is also sensitive, especially if performed repeatedly to detect changes in the amount of fluid, especially when the initial examination is equivocal. The umbilical structures should be examined closely and the urachus tracked to the bladder. Frequently a defect in the urachus or umbilicus is identified. The thorax of affected foals should also be examined, as foals with large quantities of urine in the peritoneum often have a substantial accumulation of pleural fluid. This can be important when considering anesthesia in these foals.

Radiographic examination of foals with suspected uroperitoneum is rarely performed because of the utility of ultrasonographic examination in this disease. Plain abdominal radiography is of limited usefulness in the detection of uroperitoneum or localizing the source of urine. Positive contrast cystography using a 10% solution of iophexol or similar water-soluble contrast agent administered into the bladder through a Foley catheter can be useful in detection of leaks, especially small leaks that cannot be visualized on ultrasonographic examination. Care should be taken to insure that the bladder is sufficiently distended to insure that any leak is visualized. Use of barium contrast medium or negative-contrast cystography (infusion of air into the bladder) are contraindicated. Intravenous pyelography is of very limited usefulness in the detection of ureteral defects because of the difficulty in localizing the site of the leak.

Electrocardiographic examination can reveal cardiac arrest, atrioventricular block, presumed intraventricular block, ventricular premature complexes, ventricular tachycardia and ventricular fibrillation. These abnormalities are most likely to occur in foals that are hyperkalemic at the time of induction of anesthesia.

CLINICAL PATHOLOGY

Foals with uncomplicated uroperitoneum have hyponatremia, hypercholesterolemia, hypobcarbonatemia (metabolic acidosis), acidemia, hyperkalemia, and azotemia. Severely affected foals can be profoundly hyponatremic (< 110 mEq/L) and hyperkalemic (< 7 mEq/L). Serum creatinine and urea nitrogen concentrations are elevated. When interpreting serum urea nitrogen concentrations in foals it should be borne in mind that the urea concentration in normal foals is much lower than in adults (see Table 3.6).

Diagnosis based on serum electrolyte abnormalities is confounded in hospitalized foals that are being treated with intravenous fluids. Administration of fluids prevents the development of hyponatremia and hyperkalemia in septic foals that develop uroperitoneum during the course of their disease. However, fluid administration does not prevent the increases in serum creatinine or urea nitrogen concentration.

Hematological abnormalities reflect any underlying sepsis.

Analysis of peritoneal fluid reveals that it has a low specific gravity (< 1.010), low total protein concentration (< 2.5 g/dL, 25 g/L) and low white cell count (< 1000 cells/μL, 1 x 10³ cells/L). It can have a urinous odor, but this is not a reliable diagnostic sign. Peritoneal fluid from foals with uroperitoneum has elevated concentrations of creatinine (usually twice that in a contemporaneous serum sample), urea nitrogen (twice that of serum) and potassium. Microscopic examination of the fluid can reveal calcium carbonate crystals, the presence of which is diagnostic for urine.

NECROPSY FINDINGS

Necropsy examination confirms the presence of uroperitoneum and the structural defect allowing leakage of urine into the abdomen. The defect can have signs of healing, which can make it readily confused with a malformation, because affected foals can survive for days after the rupture occurs – sufficient time for partial healing of the defect.

DIFFERENTIAL DIAGNOSIS

Demonstration of an excessive quantity of poorly echogenic fluid in the abdomen of a foal that is passing little or no urine and that has hyponatremia and hyperkalemia is diagnostic of uroperitoneum. Confirmation of the diagnosis can be achieved by measurement of creatinine concentration in the peritoneal fluid. Ultrasonographic examination greatly facilitates the diagnosis.

The principal differential diagnoses for azotemia in foals are uroperitoneum and renal disease. Primary renal disease in foals can cause hyponatremia, hyperkalemia, and azotemia, but there is no accumulation of fluid in the peritoneum. Additionally, in primary renal disease there are abnormalities in urine composition (presence of blood, protein, leukocytes, and casts). Hyponatremia and hyperkalemia can occur in foals with enterocolitis, but the other clinical signs are diagnostic of this disease. Addison’s disease (mineralocorticoid deficiency) does occur in foals but is rare, and there is no accumulation of fluid in the abdomen.

TREATMENT

Definitive treatment of uroperitoneum in foals is surgical repair of the defect. However, there is no need for surgery on an emergency basis. Rather, careful monitoring of life-threatening electrolyte and fluid abnormalities before the foal is subjected to anesthesia. Principles of medical treatment are prevention of potentially lethal cardiac arrhythmia, correction of electrolyte, fluid and acid-base abnormalities and relief of abdominal distension.
Potentially life-threatening electrolyte abnormalities, especially hyperkalemia, should be corrected urgently and before any attempted surgical correction of the anatomical defect.

Correction of fluid and electrolyte abnormalities is best achieved by draining the abdomen and insuring continued voiding of urine while administering isotonic fluids intravenously. Because the foal has normal kidney function, draining urine from the abdomen allows the foal to restore normal serum electrolyte concentrations and fluid balance provided that the foal is allowed to nurse and/or is administered parenteral fluids.

Peritoneal drainage is achieved by placement of a catheter into the abdomen. The catheter should be placed with a view to it remaining in place until the electrolyte abnormalities have been corrected and the foal is a suitable candidate for surgical repair of the anatomical defect. An ideal catheter is a Foley balloon-tipped catheter placed into the abdomen through a small (5 mm) incision in the skin and external abdominal wall. The catheter should be placed in the inguinal region and to one side of the linear alba, so as to avoid injury and contamination of a future surgical site and to minimize the chances of the catheter being plugged by omentum. The catheter is inserted under local anesthesia and the balloon is inflated to secure the catheter in the abdomen. The catheter can be further secured by a suture. Sedation or tranquilization should be avoided in foals at risk of cardia or respiratory distress because of the electrolyte abnormalities. Urine should be allowed to drain from the catheter into a closed collection system that minimizes the chances of ascending infection of the peritoneum.

Hyperkalemia is usually readily corrected by peritoneal drainage and administration of potassium-free fluid, such as 0.9% sodium chloride. Serum potassium concentration declines quickly when effective peritoneal drainage is obtained and serum potassium concentrations can normalize in 8–12 hours. If emergency management of hyperkalemia is required administration of 5% dextrose either alone or, if hyponatremia is also present, in 0.9% sodium chloride, is effective in reducing serum potassium concentration. Serum bicarbonate (1–3 mEq/kg BW, intravenously) will also decrease serum potassium concentration. Calcium gluconate (1–3 mEq/kg BW, intravenously) is used to decrease serum potassium concentration. Calcium gluconate antagonizes the effect of hyperkalemia on cardiac function and is useful in the treatment of hyperkalemic arrhythmias. The serum potassium concentration should be less than 5.5 mEq/L before the foal is anesthetized. Mare’s milk, which is rich in potassium, should be withheld until the serum potassium concentration is below the required level.

Hyponatremia is resolved by drainage of the peritoneum and administration of 0.9–1.8% sodium chloride intravenously. Serum sodium concentration, especially if markedly low, should be corrected slowly to prevent the development of hyponatremic encephalopathy. Serum sodium concentrations should be increased by approximately 1 (mEq/L)/h.

Affected foals should be administered broad-spectrum antibiotics because of the risk of peritonitis and because many foals with uroperitoneum have sepsis. The immune status of young foals should be examined by measurement of serum IgG concentrations. Those that favor the development of uroperitoneum secondary to sepsis.

Correction of the defect in the bladder or urachus is surgical. Nonsurgical management has been described in a foal in which a Foley catheter was inserted in the bladder and left in place for 5 days. The bladder was constantly drained of urine and this allowed the tear to heal. This technique offers an alternative to surgical repair of bladder rupture. However, surgical repair is definitive and is the recommended method of treatment.

Subcutaneous rupture of the urachus can similarly be treated by placement of a Foley catheter through the patent urachus and into the bladder. The defect in the urachus is then allowed to heal and the catheter is removed in 3–6 days.

PREVENTION AND CONTROL

There are no recognized means of preventing or controlling this disease. Minimizing the risk of foals developing septic disease is expected to reduce the incidence of uroperitoneum secondary to sepsis.

REFERENCES

UROLITHIASIS IN RUMINANTS

Urolithiasis is common as a subclinical disorder among ruminants raised in management systems where the ration is composed primarily of grain or where animals graze certain types of pasture. In these situations, 40–60% of animals may form calculi in their urinary tract. Urolithiasis becomes an important clinical disease of castrated male ruminants when calculi cause urinary tract obstruction, usually obstruction of the urethra. Urethral obstruction is characterized, clinically by complete retention of urine, frequent unsuccessful attempts to urinate and distension of the bladder. Urethral perforation and rupture of the bladder can be sequela. Mortality is high in cases of urethral obstruction and treatment is surgical. As a result, prevention is important to limit losses from urolithiasis.

ETIOLOGY

Urinary calculi, or uroliths, form when inorganic and organic urinary solutes are precipitated out of solution. The precipitates occur as crystals or as amorphous 'deposits'. Calculi form over a long period by a gradual accumulation of precipitate around a nidus. An organic matrix is an integral part of most types of calculi. Several factors affect the rate of urolith formation, including conditions that affect the concentration of specific solutes in urine, the ease with which solutes are precipitated out of solution, the provision of a nidus and the tendency to concretion of precipitates. These are presented under Epidemiology. Factors that contribute to the clinical syndrome of obstructive urolithiasis are dealt with separately.

EPIDEMIOLOGY

Species affected

Urolithiasis occurs in all ruminant species but is of greatest economic importance in feeder steers and wethers (castrated lambs) being fed heavy concentrate rations, and animals on range pasture in particular problem areas. These range areas are associated with the presence of pasture plants containing large quantities of oxalate, estrogens, or silica. When cattle graze pasture containing plants with high levels of silica, uroliths occur in animals of all ages and sexes. The prevalence of uroliths is about the same in cows, heifers, bulls, and steers grazing on the same pasture and they may even occur in newborn calves. Females and bulls usually pass the calculus and obstructive urolithiasis is primarily a problem in castrated male animals.

Obstructive urolithiasis is the most common urinary tract disease in breeding rams and goats.

There are three main groups of factors that contribute to urolithiasis:

- Those that favor the development of a nidus about which precipitation and concretion can occur
- Those that facilitate precipitation of solutes on to the nidus
Those that favor concretion by cementing precipitated salts to the developing calculus.

Nidus formation
A nidus favors the deposition of crystals about itself. A nidus may be a group of desquamated epithelial cells or necrotic tissue that may be formed as a result in occasional cases from local infection in the urinary tract. When large numbers of animals are affected it is probable that some other factor, such as a deficiency of vitamin A or the administration of estrogens, is the cause of excessive epithelial desquamation. When stilbestrol was used as a growth promoter, mortality rates of 20% due to obstructive urolithiasis were recorded in wethers receiving stilbestrol implants compared with no mortalities in a control group. Diets low in vitamin A have been suspected as a cause of urolithiasis but vitamin A deficiency does not appear to be a major causative factor.

Precipitation of solutes
Urine is a highly saturated solution containing a large number of solutes, many of them in higher concentrations than their individual solubilities permit in a simple solution. Several factors may explain why solutes remain in solution. Probably the most important factor in preventing precipitation is the presence of protective colloids that convert urine into a gel. These colloids are efficient up to a point, but their capacity to maintain a simple solution. Several factors may explain why solutes remain in solution. Probably the most important factor in preventing precipitation is the presence of protective colloids that convert urine into a gel. These colloids are efficient up to a point, but their capacity to maintain a simple solution may be overcome by abnormailities in one or more of a number of other factors. Even in normal animals, crystals of a number of solutes may be present in the urine intermittently and urine must be considered to be an unstable solution. The physical characteristics of urine, the amount of solute presented to the kidney for excretion and the balance between water and solute in urine all influence the ease of calculus formation. In most cases these factors can also be influenced by management practices.

The pH of urine affects the solubility of some solutes, mixed phosphate and carbonate calculi being more readily formed in an alkaline than an acid medium.

Ammonium chloride or phosphoric acid added to the rations of steers increases the acidity of the urine and reduces the incidence of calculi. The mechanism is uncertain but is probably related to the effect of pH on the stability of the urinary colloids or the effect of diuresis. In contrast, variations in pH between 1 and 8 have little influence on the solubility of silicic acid, the form of silica excreted in the urine of ruminants.

As a result, dietary supplementation with ammonium chloride does not consistently prevent the formation of siliceous calculi.

Although it is difficult to induce urolithiasis by restricting access to water, concentrated urine is a risk factor for calculus formation. Animals can be forced to produce concentrated urine because of lack of easy access to water, a particular problem in pastured animals, lack of familiarity with water delivery systems and poor quality of available water. Water deprivation can be exacerbated by heavy fluid loss by sweating in hot, arid climates.

Factors favoring concretion
Most calculi, and siliceous calculi in particular, are composed of organic matter as well as minerals. This organic component is mucoprotein, particularly its mucopolysaccharide fraction. It acts as a cementing agent and favors the formation of calculus when precipitates are present. The mucoprotein content of urine of feeder steers and lambs is increased by heavy concentrate-low roughage rations, by the feeding of pelleted rations, even more so by implantation with diethylstilbestrol and, combined with a high dietary intake of phosphate, may be an important cause of urolithiasis in this class of livestock. These high levels of mucoprotein in urine may be the result of a rapid turnover of supporting tissues in animals that are making rapid gains in weight.

Miscellaneous factors in the development of urolithiasis
Stasis of urine favors precipitation of solutes, probably by virtue of the infection that commonly follows, providing cellular material for a nidus. Certain feeds, including cottonseed meal and milo sorghum, are credited with causing more urolithiasis than other feeds. Alfalfa is in an indeterminate position: by some observers it is thought to cause the formation of calculi, by others to be a valuable aid in preventing their formation. Pelleting appears to increase calculus formation if the ration already has this tendency.

Attempts to produce urolithiasis experimentally by varying any of the above factors are usually unsuccessful and natural cases most probably occur as a result of the interaction of several factors. In feedlots a combination of high mineral feeding and a high level of mucoprotein in the urine associated with rapid growth are probably the important factors in most instances. In range animals a high intake of mineralized water, or oxalate or silica in plants, are most commonly associated with a high incidence of urinary calculi, but again other predisposing factors, including deprivation or excessive loss of water, may contribute to the development of the disease. Limited water intake at weaning...
and in very cold weather may also be a contributory factor.

Composition of calculi
The chemical composition of urethral calculi varies and appears to depend largely on the dietary intake of individual elements. In semi-arid areas such as the great plains of North America and parts of Australia, the dominant pasture grasses have a high content of silica. Cattle and sheep grazing these pastures have a high prevalence of siliceous calculi. Calculi containing calcium carbonate are more common in animals on dover-rich pasture, or when oxalate-containing plants abound. Calcium, ammonium, and magnesium carbonate are also common constituents of calculi in cattle and sheep at pasture.

Sheep and steers in feedlots usually have calculi composed of struvite, magnesium ammonium phosphate. High concentrations of magnesium in feedlot rations also cause a high prevalence of magnesium ammonium phosphate calculi in lambs. Experimental feeding of a ration with a high magnesium content increases the prevalence of calcium apatite urolithiasis in calves and can be prevented by supplementary feeding with calcium.

Oxalate calculi are extremely rare in ruminants but have been observed in goats and induced experimentally in feedlot cattle. Xanthine calculi in sheep are recorded in some areas in New Zealand where pasture is poor.

Estrogenic subterranean clover can cause urinary tract obstruction in wethers in a number of ways. Soft, moist, yellow calculi containing 2-benzocoumarins, isoflavones and indigotin–indirubin have been observed. Calculi or unformed sediments of benzocoumarins (urooliths) and 4′-O-methylxylool, either singly or in various combinations with equol, formotenin, biochanin A, indigotin and indirubin, also occur. Obstruction is promoted by estrogenic stimulation of squamous metaplasia of the urethral epithelium, accessory sex glandular enlargement and mucus secretion. Pastures containing these plants are also reputed to cause urinary obstruction by calculi consisting of calcium carbonate. Feedlot lambs receiving a supplement of stilbestrol (1 mg/kg of feed or 2 mg per lamb daily) developed urethral obstruction believed to be caused primarily by plugs of mucoprotein. The accessory sex glands were also enlarged.

Risk factors for obstructive urolithiasis
The risk factors important in the formation of urinary calculi are also important in the development of obstructive urolithiasis.

The size of individual calculi and the amount of calculus material are both important in the development of urethral obstruction. Often the obstruction is caused by one stone, although an aggregation of many small struvite calculi often causes obstruction in sheep fed high-concentrate rations.

Once calculi form, the most important factor contributing to the occurrence of obstruction is the diameter of the urethra. Wethers (castrated lambs) and steers (castrated cattle) are most commonly affected because of the relatively small diameter of the urethra in these animals. Castration has a significant impact on the diameter of the urethra in steers. When the urethral diameter of late castrates (6 months old) was compared to early castrates (2 months), it was found to be 8% larger and would be able to expel a calculus that was 13% larger than a calculus passed by early castrates. Bulls can usually pass calculi that are 44% larger than those that could be passed by an early castrated steer.

Occurrence
Urethral obstruction may occur at any site but is most common at the sigmoid flexure in steers and in the vermiform appendage or at the sigmoid flexure in wethers or rams, all sites where the urethra narrows. Urolithiasis is as common in females as in males, but obstruction rarely if ever occurs because of the shortness and large diameter of the urethra. Repeated attacks of obstructive urolithiasis are not uncommon in wethers and steers and at necropsy up to 200 calculi may be found in various parts of the tract of one animal. However, generally, a single calculus causes obstruction in cattle whereas multiple calculi are common in sheep.

In North America obstructive urolithiasis due to siliceous calculi is most common in beef feeder cattle during the fall and winter months. The calves are weaned at 6–8 months and moved from pasture to a feedlot where they are fed roughage and grain. The incidence of obstructive urolithiasis is highest during the early part of the feeding period and during cold weather, when the consumption of water may be decreased.

Although the occurrence of obstructive urolithiasis is usually sporadic, with cases occurring at irregular intervals in a group of animals, outbreaks may occur affecting a large number of animals in a short time. In outbreaks it is probable that factors are present that favor the development of calculi, as well as the development of obstruction. For example, multiple cases of obstructive urolithiasis can occur in lambs within a few weeks of introducing a concentrated ration. Obstructive urolithiasis increases in occurrence with age but has occurred in lambs as young as 1 month of age.

PATHOGENESIS
Urinary calculi are commonly observed at necropsy in normal animals, and in many appear to cause little or no harm. Calculi may be present in kidneys, ureters, bladder, and urethra. In a few animals pyelonephritis, cystitis, and urethral obstruction may occur. Obstruction of one ureter may cause unilateral hydronephrosis, with compensation by the contralateral kidney. The major clinical manifestation of urolithiasis is urethral obstruction, particularly in wethers and steers. This difference between urolithiasis and obstructive urolithiasis is an important one. Simple urolithiasis has relatively little importance but obstructive urolithiasis is a fatal disease unless the obstruction is relieved. Rupture of the urethra or bladder occurs within 2–3 days if the obstruction is not relieved and the animal dies of uremia or secondary bacterial infection. Rupture of the bladder is more likely to occur with a spherical, smooth calculus that causes complete obstruction of the urethra. Rupture of the urethra is more common with irregularly shaped stones that cause partial obstruction and pressure necrosis of the urethral wall.

CLINICAL FINDINGS
Calculi in the renal pelvis or ureters are not usually diagnosed antemortem although obstruction of a ureter may be detectable on rectal examination, especially if it is accompanied by hydronephrosis. Occasionally the exit from the renal pelvis is blocked and the acute distension that results may cause acute pain, accompanied by stiffness of the gait and pain on pressure over the loins. Calculi in the bladder may cause cystitis and are manifested by signs of that disease.

Obstruction of the urethra by a calculus
This is a common occurrence in steers and wethers and causes a characteristic syndrome of abdominal pain with kicking at the belly, treading with the hind feet and swishing of the tail. Repeated twitching of the penis, sufficient to shake the prepuce, is often observed, and the animal may make strenuous efforts to urinate, accompanied by straining, grunting and grating of the teeth, but these result in the passage of only a few drops of bloodstained urine. A heavy precipitate of crystals is often visible on the preputial hairs or on the inside of the thighs. Some animals with urethral obstruction will have a dry prepuce because of the absence of urination, although this sign is not specific for urolithiasis.
The passage of a flexible catheter up the urethra, after relaxing the penis by lumbosacral epidural anesthesia, by pudendal nerve block or by administering an ataractic drug, may make it possible to locate the site of obstructions that are anterior to the sigmoid flexure. However, catheterization of the urethra from the glans penis to the bladder is almost impossible in cattle and ruminants because of the urethral diverticulum with its valve.7 A precurred coronary catheter has been used to catheterize the bladder of calves and goats but requires fluoroscopic guidance.

Cattle with incomplete obstruction – 'dribblers' – will pass small amounts of bloodstained urine frequently. Occasionally a small stream of urine will be voided followed by a complete blockage. This confuses the diagnosis. In these the calculus is triangular in shape and allows small amounts of urine to move past the obstruction at irregular intervals. However, these are rare.

The entire length of the penis must be palpated for evidence of a painful swelling from the preputial orifice to the scrotum, above the scrotum to locate the presence of an attachment from the prepubertal sheep and goats because of extrusion of the penis is difficult in calves and goats but requires fluoroscopic guidance.

In rams, bucks, and wethers the urethral process of the exteriorized penis must be examined for enlargement and the presence of multiple calculi. Extrusion of the penis is difficult in prepubertal and goats because of the presence of an attachment from the prepuce to the glans penis; loss of this attachment is mediated by testosterone and is usually complete by the onset of puberty, although separation may not occur in castrated animals.9 Penile extrusion is facilitated by xylazine sedation and positioning the animals with lumbosacral flexion. Abnormal urethral processes should be amputated and in many animals grist is detected during urethral transection.

On rectal examination, when the size of the animal is appropriate, the urethra and bladder are palpably distended and the urethra is painful and pulsates on manipulation.

In rams with obstructive urolithiasis, sudden depression, inappetence, stamping the feet, tail swishing, kicking at the abdomen, bruxism, anuria or the passage of only a few drops of urine are common. Clinical examination must include inspection of the ventral abdomen for edema, inspection and palpation of the preputial orifice for crystals, palpation of the penis in the area of the sigmoid flexure, and inspection and palpation of the urethral process (vermiform appendage) of the exteriorized penis.

Rupture of urethra or bladder
If the obstruction is not relieved, urethral rupture or bladder rupture usually occurs within 48 hours. With urethral rupture, the urine leaks into the connective tissue of the ventral abdominal wall and prepulse and causes an obvious fluid swelling, which may spread as far as the thorax. This results in a severe cellulitis and toxemia. The skin over the swollen area may slough, permitting draining, and the course is rather more protracted in these cases. When the bladder ruptures there is an immediate relief from discomfort but anorexia and depression develop as uremia develops. Two types of bladder rupture have been described; multiple pinpoint perforations in areas of necrosis or discrete tears in the bladder wall. The site of leakage is almost always on the dorsal aspect of the bladder. Complete urethral obstruction therefore results in urethral rupture or bladder rupture and never both in the same animal, because pressure is released once rupture occurs.

A fluid wave is detectable on tactile percussion and the abdomen soon becomes distended. The animal may continue in this state for as long as 2–3 days before death occurs. Fibrin deposition around the dorsal surface of the bladder may be palpated per rectum in steers. In rare cases death occurs soon after rupture of the bladder as a result of severe internal hemorrhage.

In rare cases calculi may form in the prepuce of steers. The calculi are top-shaped and, by acting as floating valves, cause obstruction of the prepuce orifice, distension of the prepuce and infiltration of the abdominal wall with urine. These cases may be mistaken for cases of urethral perforation.

CLINICAL PATHOLOGY
Urinalysis
Laboratory examinations may be useful in the diagnosis of the disease in its early stages when the calculi are present in the kidney or bladder. The urine usually contains erythrocytes and epithelial cells and a higher than normal number of crystals, sometimes accompanied by larger aggregations described as sand or sabulous deposit. Bacteria may also be present if secondary invasion of the traumatic cystitis and pyelonephritis has occurred.

Serum biochemistry
Serum urea nitrogen and creatinine concentrations will be increased before either urethral or bladder rupture occurs and will increase even further afterwards. Rupture of the bladder will result in uroabdomen. Because urine has a markedly low sodium and chloride concentration and high osmolality relative to plasma, equilibration of electrolytes and free water into the abdomen will always result in hyponatremia, hyperchloremia, hyperphosphatemia, and hypo-osmolality in serum, with the magnitude of the changes reflecting the volume of urine in the abdomen. Similar changes in serum biochemistry are present in steers with ruptured urethra, with the magnitude of the changes being smaller than in steers with ruptured bladder.10 Interestingly, steers with ruptured bladder or urethra typically have serum potassium concentrations within the normal range;11 this result most probably reflects the combined effects of increased saline potassium loss in the face of hyponatremia and inappetence.11

Abdominocentesis and needle aspirate of subcutaneous tissue
Abdominocentesis is necessary to detect uroperitoneum after rupture of the bladder or needle aspiration from the subcutaneous swelling associated with urethral rupture. However, it is often difficult to identify the fluid obtained from the peritoneal cavity or the subcutaneous tissues as urine other than by appearance and smell, or by biochemical examination. Generally, in uroperitoneum, substantial quantities of fluid can be easily obtained by abdominocentesis. Warming the fluid may facilitate detection of the urine odor, although this is a subjective and poorly sensitive diagnostic test.

Ultrasonography
Ultrasonography is a useful aid for the diagnosis of obstructive urolithiasis in rams.12 All parts of the urinary tract must be examined for urinary calculi. The kidneys are examined from the paralumbar fossa and the bladder and urethra transrectally. The kidneys are examined for enlargement, and the renal pelves, medullary pyramids and urethra for dilatation. The size of the bladder should be noted and its contents examined. A ruptured bladder does not always empty completely. In rams with obstructive urolithiasis, the urethra and bladder are markedly dilated. Because of severe cystitis, the contents of the bladder appear as multiple, tiny, uniformly distributed echoes. The renal pelves are commonly dilated. Uroperitoneum may also be visualized.

Necropsy Findings
Calculi may be found in the renal pelvis or bladder of normal animals, or of those dying of other diseases. In the renal pelvis they may cause no abnormality, although in occasional cases there is accompanying pyelonephritis. Unilateral ureteral obstruction is usually accompanied by dilatation of the ureter and hydronephrosis. Bilateral obstruction causes fatal uremia. Calculi in
the bladder are usually accompanied by varying degrees of chronic cystitis. The urethra or urethral process may be obstructed by one or more stones, or may be impacted for up to 35 cm with a fine sable deposit.

When rupture of the urethra has occurred the urethra is eroded at the site of obstruction and extensive cellulitis and accumulation of urine are present in the ventral abdominal wall. When the bladder has ruptured the peritoneal cavity is distended with urine and there is mild to moderate chemical peritonitis. In areas where urolithiasis is a problem it is an advantage to determine the chemical composition of the calculi.

**TREATMENT**

The treatment of obstructive urolithiasis is primarily surgical. Cattle or lambs with obstructive urolithiasis that are near the end of their feedlot feeding period and close to being marketed can be slaughtered for salvage if the result of an antemortem inspection is satisfactory. Animals in the early stages of obstruction before urethral or bladder rupture will usually pass inspection at an abattoir. The presence of uremia warrants failure to pass inspection. Rams, bucks, and wethers will only have their glans penis exteriorized and inspected, and the urethral process amputated.

It used to be thought that calculi cannot be dissolved by medical means, but recent studies suggest that administration of specific solutions into the bladder can rapidly dissolve most uroliths. Successful outcomes have occurred following instillation of 30-200 mL of an acidic acetic solution (Walpole's buffer, pH adjusted to 4.3-4.8) or hemiacidrin solution through a cystotomy catheter; hemiacidrin is an acetic gluconocitrate solution with magnesium carbonate that is used for dissolution of magnesium ammonium phosphate and calcium phosphate uroliths in humans. The advantage of hemiacidrin is that it is reportedly less irritating to urothelium than other acids of similar pH. The cystotomy tube can be placed surgically or transcutaneously, using abdominal ultrasound. The latter technique involves placement of a 12-French sleeved trocar into the lumen of the bladder, followed by removal of the trocar and placement of a 10-French silicone Foley catheter through the sleeve of the trocar into the lumen of the bladder. The balloon on the Foley catheter is then inflated using 0.9% NaCl, the trocar sleeve removed from the abdomen and the Foley catheter secured to the abdomen. The cystotomy catheter provides an alternative route for urine to leave the bladder and is allowed to continuously drip. The cystotomy catheter is occluded for 30 minutes to 2 hours after infusion to retain the solution in the bladder and urethra, after this time the solution is drained from the bladder via the cystotomy tube.

In early stages of the disease or in cases of incomplete obstruction, treatment with smooth muscle relaxants such as phenothiazine derivatives (aminopromazine, 0.7 mg/kg of BW) has been tried to relax the urethral muscle and permit passage of the obstructing calculus; however, treatment efficacy is unknown. Animals treated medically should be observed closely to insure that urination occurs and that obstruction does not recur. However, field observations indicate that these relaxants are ineffective, and it is difficult to believe that smooth muscle relaxants could be efficacious given that the urethral and periurethral tissue contains very little smooth muscle. A more rational treatment is infiltration of local anesthetic around the origin of the retractor penile muscles or a pudendal nerve block, which would relax the retractor penis muscle and straighten the sigmoid flexure, thereby creating a wider and straighter urethral passageway.

Normograde hydrodystension is only occasionally successful, although it is frequently used as part of the initial treatment. This technique involves catherization of the urethral orifice with a suitably sized urinary catheter, and intermittent injection of 0.9% NaCl into the urethra in an attempt to flush out the calculi. Frequently, a gritty feeling is detected during this procedure, and one usually is left with the impression that the procedure is creating additional urethral trauma that may contribute to urethral stricture. Normograde hydrodystension may also pack small crystals more tightly into the urethra. In young ruminants, it can be difficult to exteriorize the glans penis and identify the urethral orifice. Cystotomy and retrograde hydrodystension appear to have a higher success rate than normograde hydrodystension.

Surgical treatment includes perineal urethrostomy to relieve bladder pressure and for the removal of calculi. This is a salvage procedure and treated animals can be sent to slaughter for salvage when they have recovered sufficiently to pass antemortem inspection. In a series of 85 cases of surgical treatment of urethral obstruction in cattle, only 35% of animals recovered satisfactorily. In small ruminants, which invariably have multiple calculi, amputation of the urethral process may restore urine flow but usually provides only temporary relief, and the long-term prognosis in sheep and goats is poor because there is a high rate of recurrence of obstruction with stricture formation at the urethrostomy site. If perineal urethrostomy is unsuccessful, tube cystotomy is indicated. Urethroscopy and laser lithotripsy have successfully dissolved uroliths in a small number of small ruminants and one steer, but the technique is expensive and not widely available. Prepubic urethrostomy has been performed in a small number of small ruminants that have undergone stricture formation following perineal urethrostomy, whereas urinary bladder marsupialization offers a simpler surgical method for correction. There is one report of erection failure in a male goat as a sequela to obstructive urolithiasis; erection failure was attributed to vascular occlusion.
of the corpus cavemosum penis. Surgical correction of urethral dilatation associated with the urethral recess in cattle has been described.

**PREVENTION**

A number of agents and management procedures have been recommended in the prevention of urolithiasis in feeder lambs and steers. First, and probably most important, the diet should contain an adequate balance of calcium and phosphorus to avoid precipitation of excess phosphorus in the urine. This is the major difficulty in controlling urolithiasis in feedlot ruminants, because their diets are grain (and therefore phosphorus)-rich. The ration should have a Ca:P ratio of 1.2:1, but higher calcium inputs (1.5–2.0:1) have been recommended. Every practical effort must be used to increase and maintain water intake in feeder steers that have just been moved into a feedlot situation. The addition of salt at the level of 4% of the total ration of feeder calves has been shown experimentally to have this effect on both steers and lambs. Under practical conditions salt is usually fed at a concentration of 3–5%, higher concentrations causing lack of appetite. It is thought that supplementary feeding with sodium chloride helps to prevent urolithiasis by decreasing the rate of deposition of magnesium and phosphate around the nidus of a calculus, but it is possible that salt-related diuresis may also play an important role. Feeding of pelleted rations may predispose to the development of phosphate calculi (such as struvite or apatite) by reducing the salivary secretion of phosphorus.

The control of siliceous calculi in cattle which are fed native range grass hay, which may contain a high level of silica, is dependent primarily on increasing the water intake. The feeding of alfalfa hay is considered to increase urine flow and lower the incidence of urolithiasis but the important reason may be that it contains considerably less silica. As in feedlot animals, water intake can be promoted by supplementing the ration with salt. For yearling (300 kg) steers the daily consumption of 50 g of salt does not prevent the formation of siliceous calculi; at 200 g daily intake the occurrence of calculi is significantly reduced, and at 300 g daily calculus formation is almost eliminated. For calves on native range, providing supplements ('creep feeds') containing up to 12% salt is effective in eliminating siliceous calculi. This effect is due to the physical diluting effect of increased water intake promoted by salt supplementation. If the calves consume sufficient quantities of salt to increase the water intake above 200 g/kg BW per day the formation of siliceous calculi will be completely suppressed. Since siliceous calculus form in the last 60 days before weaning, it is recommended that calves on range be started on creep feed without salt well before weaning and, once calves are established on the supplement, that the salt concentration be gradually increased to 12%. It is usually necessary to increase the salt gradually to this level over a period of several weeks and incorporate it in pellets to facilitate mixing.

An alkaline urine (pH > 7.0) favors the formation of phosphate-based stones (struvite, apatite) and calcium-carbonate-based stones. Feeding an agent that decreases urine pH will therefore protect against phosphate-based stones. The feeding of ammonium chloride (45 g/d to steers and 10 g daily to sheep) may prevent urolithiasis due to phosphate calculi, but the magnitude of urine acidification achieved varies markedly depending on the acidogenic nature of the diet. For this reason, urine pH should be closely monitored when adding ammonium chloride to the ration, because clinically relevant metabolic acidosis, depression and inappetence can result from over-zealous administration rates. For range animals, ammonium chloride can be incorporated in a protein supplement and fed at about two-thirds of the above dosage. An acidic urine (pH < 7.0) favors the formation of silicate stones, so ammonium chloride manipulation of urine pH is not indicated in animals at risk of developing siliceous calculi. However, ammonium chloride may prevent the formation of silica calculi in sheep; this may have been due to the urinary diluting effects of additional chloride intake.

When the cause of urolithiasis is due to pasture exposure, females can be used to graze the dangerous pastures since they also occur in the renal pelvis, ureters, and urethra. In most cases, there is a single discrete stone, but a sandy sludge accumulates in cases of paralysis of the bladder. The prevalence is low at about 0.04–0.5% of all horse accessions or diagnoses. Animals from about 5–15 years of age and older are most commonly affected and 76% are males (27% intact, 49% geldings) and 24% females. The uroliths are most commonly in the bladder (cystic) although they also occur in the renal pelvis, ureters, and urethra. In most cases, there is a single discrete stone, but a sandy sludge accumulates in cases of paralysis of the bladder. Almost all equine uroliths are composed of calcium carbonate in the form of calcite and their ultrastructure has been examined. The factors that contribute to urolith formation in horses are not understood. Urine from healthy adult horses is characterized by a substantial quantity of mucoprotein, a high concentration of

**UROLITHIASIS IN HORSES**

Urolithiasis occurs sporadically in horses. The prevalence is low at about 0.04–0.5% of all horse accessions or diagnoses. Animals from about 5–15 years of age and older are most commonly affected and 76% are males (27% intact, 49% geldings) and 24% females. The uroliths are most commonly in the bladder (cystic) although they also occur in the renal pelvis, ureters, and urethra. In most cases, there is a single discrete stone, but a sandy sludge accumulates in cases of paralysis of the bladder. Almost all equine uroliths are composed of calcium carbonate in the form of calcite and their ultrastructure has been examined. The factors that contribute to urolith formation in horses are not understood. Urine from healthy adult horses is characterized by a substantial quantity of mucoprotein, a high concentration of
minerals, considerable insoluble sabulous material, and alkalinity. Equine urine is normally supersaturated with calcium carbonate and crystals of calcium carbonate are usually present; this is related in some manner with the occurrence of calcium carbonate uroliths in horses. Nephrolithiasis may arise as a sequel to degenerative or inflammatory processes in the kidney in which inflammatory debris serves as a nidus for calculus formation.6

**The clinical findings** of urolithiasis in the horse include:

- Stranguria (straining to urinate)
- Pollakiuria (frequent passage of small amounts of urine), hematuria and dysuria (difficult urination)
- Incontinence resulting in urine scalding of the perineum in females or of the medial aspect of the hindlimbs in males
- Painful urination with hematuria associated with cystitis
- Bacterial infection is common.7

The bladder wall may be thickened and large calculi in the bladder may be palpable per rectum, just as the hand enters the rectum. Large calculi may be observed using transrectal ultrasonography6 and cystoscopy. Calculi may also be palpated in the ureters, per rectum, or enlarged ureters may be present.1

**In males,** urethral calculi may present with signs of complete or partial obstruction that may be confused with colic of gastrointestinal origin. Horses with urethral obstructions make frequent attempts to urinate but pass only small amounts of blood-tinged urine. Unless rupture has occurred, the bladder is grossly enlarged. The calculus can be located by palpation of the penile urethra and by passage of a lead wire or catheter. If a catheter or lead wire is passed, care should be taken to prevent damage to the urethral mucosa. Bladder rupture leads to uroperitoneum but, if the rupture occurs at the neck of the bladder, urine may accumulate retroperitoneally and produce a large, diffuse, fluid swelling that is palpable per rectum. When rupture occurs acute signs disappear and are replaced by depression, immobility and pain on palpation of the abdominal wall. The heart rate rises rapidly and the temperature falls to below normal.

Urination reveals evidence of erythrocytes, leukocytes, protein, amorphous debris, and calcium carbonate crystals.

Renal calculi are frequently bilateral and affected animals have often progressed to chronic renal failure by the time of diagnosis without having displayed signs of urinary tract obstruction.6 A history of chronic weight loss and colic in a horse with renal failure indicates the possible presence of renal calculi. Treatment is supportive as for all cases of chronic renal failure.

**Treatment** for cystic calculi is surgical removal of the calculus and correction of any defect in the bladder. Perineal urethrostomy has been used for removal of cystic calculi in a gelding.5 Urethral calculi in males are removed through the external urethral orifice or by urethrostomy at the site of obstruction. Recurrence of cystic and urethral calculi is common in the horse, which may be related to the failure to remove all calculi. Some cystic calculi can be removed with the aid of electrohydraulic lithotripsy,9 laser lithotripsy under endoscopic visualization10 or surgery. In large mares with bladder calculi, it is possible to remove the calculi manually by passing a very small hand through the urethra into the bladder and retrieving the calculi after administration of epidural analgesia and sedation. Percutaneous nephrostomy of the right kidney under ultrasonic guidance has been used for short-term diversion of urine in a horse with ureteral calculi.2 Ammonium chloride, at 200 mg/kg BW orally twice daily and decreased at biweekly intervals until a dosage of 60 mg/kg BW is reached, is recommended to maintain the urine pH below 7.0.

**URETHRAL TEARS IN STALLIONS AND GELDINGS**

Urethral rents are lesions in the convex surface at the level of the ischial arch in geldings and stallions. The lesions communicate with the corpus spongiosum and cause hemorrhage at the end of urination in geldings or during ejaculation by stallions.1 Stallions do not have hematuria, despite having a lesion identical to that in geldings, presumably because of the lower pressure in the corpus spongiosum of stallions at the end of urination compared to that in geldings.2 The disease is apparently caused by contraction of the bulbospongiosus muscle at the end of urination, with a consequent increase in pressure in the corpus spongiosum and expulsion of blood through the rent. The cause of the rent has not been determined. The diagnosis is confirmed by endoscopic examination of the urethra with visualization of the rent in the urethral mucosa. Treatment of the disease is by temporary subischial urethrostomy and sexual rest. Sexual rest alone was successful in one stallion.1

**URINARY BLADDER NEOPLASMS**

Tumors of the urinary bladder are common only in cattle, where they are associated with bracken poisoning, but they do occur in other circumstances. For example, 18 cows are recorded in one series, with angioma, transitional epithelial carcinoma and vascular endotheloma being the most common tumors. Abattoir surveys in Canada, the USA, and Australia identified papillomas, lymphomas, adenomas, hemangiomata, and transitional cell tumors occurring at low frequencies in slaughtered cattle.1,2 Papillomas appear to be associated with the bovine papillomavirus (BPV-5). Most bladder neoplasms develop from focal areas of hyperplasia within the transitional cell layer and approximately 80% of these can be classified as carcinomas while 17% are papillomas. Because these neoplasms arise from a common site, they can be very similar in gross and histological appearance and very difficult to differentiate.3 The immunoenzymatic labeling of intermediate filaments in bovine urinary bladder tumors is an accurate indicator of histogenesis.

Six cases of bladder neoplasia are also recorded in horses.6 Clinical signs included hematuria, weight loss, stranguria and the secondary development of cystitis.

**Congenital defects of the urinary tract**

Congenital defects of the urinary tract are not common in farm animals. The most common congenital defect is uroperitoneum in foals following rupture of the urinary bladder.

**RENAL HYPOPLASIA**

Developmental abnormalities of the kidneys are classified as renal agenesis, hypoplasia and dysplasia, with agenesis...
and hypoplasia representing different degrees of the same condition. Renal hypoplasia is defined as a decrease in total renal parenchyma of one-third or more, with a proportionately greater loss of medullary than cortical tissue. The diagnosis of renal hypoplasia is straightforward in neonates but can be difficult to differentiate from renal dysplasia in adults.

Bilateral renal hypoplasia with or without agenesis is recorded in Large White piglets, the piglets being dead at birth or dying in the first 3 months of life. Clinical signs exhibited by older pigs included lethargy, shivering, anorexia, diarrhea and a slow rate of growth. The disease was suspected to be inherited in a simple autosomal recessive manner and the basic defect appeared to be failure of development of mesonephric mesenchyme.

Cases of bilateral renal hypoplasia have been recorded in four horses. The four horses were 1 day to 3 years of age and had common histories of stunting, poor growth rate, anorexia, depression, and lethargy. Evidence of chronic renal failure was present on clinical pathological examination. Transrectal and transabdominal ultrasonography revealed small kidneys and small renal medulla and pelves and was considered a useful diagnostic test.

RENA L DYSPL ASIA

Renal dysplasia is defined as disorganized development of the renal parenchyma due to anomalous differentiation. Histologically, renal dysplasia is characterized by persistence of abnormal mesenchymal structures, including undifferentiated cells, cartilage, immature collecting ductules, and abnormal lobar organization.

Renal dysplasia with benign ureteropelvic polypos associated with hydro nephrosis has been recorded in a 4-month-old foal. Renal dysplasia has also been diagnosed in two adult horses with weight loss, azotemia, hypercalcemia and increased fractional clearance of sodium. Ultrasonographic examination of the kidneys revealed a poor distinction between the cortex and medulla due to a hyperechoic medulla, which was due to fibrosis. Histological changes in both horses were indicative of interruption of nephrogenesis after the initiation, but before the complete differentiation, of the metanephric blastema. Renal dysplasia is also reported in foals, both as an apparent spontaneous disease and in foals born to mares treated with sulfadimidine, pyrimethamine, and folic acid during pregnancy.

Congenital renal dysplasia has been recorded in two successive years in a Leicester sheep flock crossbred with Suffolk and Swaledale rams. Affected lambs were born alive, were reluctant to stand or move, sucked poorly and had wet coats. Lambs improved with nursing and provision of warmth, but none with clinical signs at birth survived beyond 5 days after birth. At necropsy, the kidneys were bilaterally small with fine intracortical cysts and distinct cortical and medullary zones. An inherited dominant trait with complete penetrance is suspected.

Renal tubular dysplasia has been diagnosed in Japanese Black cattle (wagyu) with renal failure, poor growth and long hooves. Calves were undersized at birth and had repeated episodes of diarrhea during the neonatal period. Calves began to show signs of growth retardation from 2-5 months of age and had a normal appetite. Clinicopathological findings included azotemia, increased serum phosphorus concentrations and oliguria. At necropsy, the main lesion was dysplasia of the proximal tubule epithelial cells, with secondary interstitial fibrosis with a reduction in the numbers of glomeruli and tubules in older cattle. An autosomal recessive mode of inheritance has been determined associated with a deletion of the paracellin-1 gene on chromosome 1. This gene encodes a protein that is part of the tight junction of renal epithelial cells, and this gene deletion is considered to be the cause for the renal tubular dysplasia. Heterozygotes are clinically normal and have normal renal function.

POLYCYSTIC KIDNEYS

In most species this is a common congenital defect. If it is extensive and bilateral the affected animal is usually stillborn or dies soon after birth. In some cases, bilateral defects are compatible with life and clinical signs may not present until the residual nephron mass is gradually exhausted and the animal is adult. If it is unilateral no clinical signs appear because of compensatory activity in the other kidney, but in an adult the enormously enlarged kidney may be encountered during rectal examination.

In adult horses, polycystic disease may also be acquired rather than congenital. The disease is rare, but affected animals present in varying stages of chronic renal failure. A high incidence of renal defects has been recorded in suckling pigs from sows vaccinated during early pregnancy with attenuated hog cholera virus; bilateral renal hypoplasia has been observed as a probably inherited defect in Large White pigs. Most polycystic kidneys in pigs appear to be inherited in a polygenic manner and have no effect on the pig's health or renal function. However, there is a record of the defect in newborn pigs in one herd in which it caused gross abdominal distension due to moderate ascites and gross cystic distension of the kidneys and tract. There was no evidence that the disease was inherited in this instance and a toxic origin was surmised.

Isolated cysts occur in the kidneys of all species and are of no clinical significance. The increased availability of ultrasonographic examination of the kidneys of animals facilitates antemortem identification of these cysts. The cysts are usually solitary and unilateral.

Congenital polycystic kidney disease of lambs occurs as an autosomal recessive trait. The disease is recognized in Romney, Perendale, and Coopworth sheep in New Zealand. Lambs die at or shortly after birth and there is no apparent sex predisposition. Necropsy examination reveals an abdomen distended by the enlarged kidneys, which contain large numbers of fluid-filled 1-5 mm cysts. There are gross and histological abnormalities of the liver and pancreas. A pathologically similar disease is reported in a Nubian goat.

ECTOPIC URETER

Ectopic ureter has been recorded in cattle and horses. The condition may be unilateral or bilateral with urinary incontinence present since birth as the major clinical manifestation. Reported neurogenic causes of urinary incontinence in horses include cauda equina neuritis, herpesvirus-1 myelitis, Sudan grass toxicosis, sorghum poisoning, trauma, and neoplasia. Nonneurogenic causes of urinary incontinence in horses include ectopic ureter, cystitis, urolithiasis, hyperestrogenism, and abnormal vaginal conformation.

The ectopic ureter opens into the urogenital tract at a place other than the bladder such as the cervix, urethra, or vagina. The condition is often complicated by ascending infections, hydrenephrosis, and dilatation of the ureter. Definite diagnosis requires excretory urography or endoscopy; visualization of the ureteral openings during endoscopy can be assisted by intravenous administration of phenolsulphonphthalein (0.01 mg/kg BW) or indigo carmine (0.25 mg/kg BW) to impart a red or blue color, respectively, to the urine being produced. Surgical treatment involving ureterovesical anastomosis or unilateral nephrectomy has been successful.

URETERAL DEFECT

Unilateral and bilateral ureteral defects have been reported in newborn foals.
The clinical presentation is similar to rupture of the urinary bladder but urethral defects may be more common in filly foals than in colts.21

**PATENT URACHUS**

Failure of the urachus to close at birth occurs most commonly in foals and is very rare in other species. Patent urachus occurs as three syndromes in foals: congenital and present at birth; acquired and secondary to urachal infection or inflammation; or secondary to severe systemic illness, usually sepsis. As a result of the patent urachus, which during intrauterine life drains urine into the allantoic fluid, urine leaks from the umbilicus. The urine flow varies from a continuous stream during micturition to constant or intermittent dribbling, or a continuous moistening of the umbilical stalk. Healthy foals with congenital patent urachus heal in several days and no specific treatment is required. Formerly, cauterization with phenol or silver nitrate was practiced, but this treatment has the potential to induce necrosis and increases susceptibility to infection.

Foals with patent urachus secondary to umbilical disease usually have an enlarged umbilicus and some have a purulent discharge. Foals that have patent urachus secondary to other umbilical disease might require surgical correction, although most respond to a 7-14 day course of antimicrobials. Foals with patent urachus secondary to systemic disease, usually sepsis, should have their other disease treated aggressively and the urachus allowed to close spontaneously, which it usually does. Ultrasonographic examination of the umbilicus of all foals with patent urachus is essential to determine the extent of disease and presence of intra-abdominal disease. As with all sick foals, the immune status of foals with patent urachus secondary to umbilical or systemic disease should be determined by measurement of serum IgG concentration and foals with low serum IgG concentration should receive a transfusion. Cystitis is an occasional sequel but omphalitis and urachal abscess may also develop as complications. Patent urachus with a perforated urethra has been recorded in a lamb.22

Urachal abscess is discussed as a subgroup of umbilical abscess in Chapter 3. When the infection is localized in the urachus there are usually signs of cystitis, especially increased frequency of urination.23

**EVESION OF THE BLADDER**

Umbilical evagination of the bladder has been reported in a neonatal filly.24 The bladder prolapsed through the umbilicus such that the mucosa of the bladder was outermost (bladder eversion). Bladder eversion through the urethra into the vagina and through the vulva occurs in mares immediately after parturition. In this instance care must be taken not to mistake the everted bladder for uterine tissue.25 Correction in both instances is surgical.

**RUPTURE OF THE BLADDER**

Rupture of the bladder is dealt with above, under other causes of uroperitoneum in foals.

**URETHRAL DEFECT**

An anomalous vas deferens caused a chronic partial urethral obstruction in a 2-year-old Limousin bull, resulting in bilateral hydronephrosis, pyelonephritis of the left kidney, and bilateral ureteral dilatation.26 There are two reports of a ruptured urinary bladder in neonatal calves apparently due to a congenital urethral obstruction that was corrected by passing a urethral catheter. Congenital urethral obstruction with subsequent hydronephrosis and uroperitoneum is reported in a lamb.27

**URETHRAL ATRESIA**

This is recorded rarely in calves and is manifested by failure to pass urine and distension of the patent portion of the urethra.28

**HYPOSPADIAS**

Imperfect closure of the external male urethra in a series of newborn lambs is recorded with other neonatal defects including atresia ani and diaphragmatic hernia. No genetic influence was suspected and the cause was unidentified.29

Introduction

This chapter presents the principles of clinical neurology and their application to large animal practice. In general, this activity has not kept pace with the study of neurology in humans and small animals, although remarkable progress has been made in equine neurology over the last 20 years. To a large extent this shortfall is due to the failure of large animal clinicians to relate observed clinical signs to a neuroanatomical location of the lesion. In many cases this failure has been because of adverse environmental circumstances, or the large size or nature of the animal, all of which adversely impact the quality of the neurological examination. It may be very difficult to do an adequate neurological examination on an ataxic belligerent beef cow that is still able to walk and attack the examiner. An aggressive, paretic bull in broad sunlight can be a daunting subject if one wants to examine the pupillary light reflex; ophthalmoscopic examination of the fundus of the eye in a convulsing steer in a feedlot pen can be an exasperating task. Thus, at one end of the spectrum is the clinical examination of pigs affected with nervous system disease, which is limited to an elementary clinical examination and necropsy examination.1 At the other end, neurological examination of the horse with nervous system disease is very advanced. The global occurrence of bovine spongiform encephalopathy has highlighted the importance of accurate clinical diagnosis in adult cattle with neurological abnormalities.

Discrete lesions of the central nervous system resulting in well-defined neurological signs are not common in agricultural animals. Many of the diseases are characterized by diffuse lesions associated with viruses, bacteria, toxins, nutritional disorders and embryological defects, and the clinical findings of each disease are similar. Rather than attempting to localize lesions in the nervous system, large animal practitioners more commonly devote much of their time to attempting to identify whether an animal has meningoencephalitis, as in Histophilus somni meningoencephalitis; whether it has diffuse brain edema or increased intracranial pressure, as in polioencephalomalacia; or whether the dysfunction is at the neuromuscular level, as in hypomagnesemic tetany.

Radiographic examination, including myelography, is not used routinely or available as a diagnostic aid in large animal practice. The collection of cerebrospinal fluid (CSF) from the different species and ages of large animal without contaminating the sample with blood is a technique that few large-animal veterinarians have mastered. However, the collection of CSF from the lumbosacral cistern is not difficult if the animals are adequately restrained, and the information obtained from analysis of CSF can be very useful in the differential diagnosis...
Referral veterinary centers are now providing detailed neurological examinations of horses with nervous system disease and the clinical and pathological experience has expanded the knowledge base of large-animal clinical neurology.

In spite of the difficulties, the large animal practitioner has an obligation to make the best diagnosis possible using the diagnostic aids available. The principles of large-animal neurology are presented in this chapter and the major objective is to recognize the common diseases of the nervous system by correlating the clinical findings with the location and nature of the lesion. Accurate neuroanatomical localization of the lesion(s) remains the fundamental requirement for creating a differential diagnosis list and diagnostic and treatment plan.

A disease such as rabies has major public health implications and it is important for the veterinarian to be able to recognize the disease as early as possible and to minimize human contact. It is also important to be able to recognize treatable diseases of the nervous system such as polioencephalomalacia, listeriosis and nervous ketosis, and to differentiate them from untreatable and globally important diseases such as bovine spongiform encephalopathy.

The nontreatable diseases must also be recognized as such, and slaughter for salvage or euthanasia recommended if necessary. There must be a major emphasis on prognosis because it is inhumane and uneconomic to hospitalize or continue to treat an adult cow or horse with incurable neurological disease for an indefinite period. If they are recumbent the animals commonly develop secondary complications such as decubitus ulcers and other self-inflicted injuries because of repeated attempts to rise. Very few diseases of the nervous system of farm animals are treatable successfully over an extended period of time. This has become particularly important in recent years with the introduction of legislation prohibiting the slaughter of animals that have been treated with antibiotics until after a certain withdrawal period, which may vary from 5–30 days. This creates even greater pressure on the clinician to make a rapid, inexpensive and accurate diagnosis and prognosis.

Because of limitations in the neurological examination of large animals, there must be much more emphasis on the history and epidemiological findings. Many of the diseases have epidemiological characteristics that give the clinician a clue to the possible causes, thus helping to narrow the number of possibilities. For example, viral encephalomyelitis of horses occurs with a peak incidence during the insect season, lead poisoning is most common in calves after they have been turned out on to pasture, and polioencephalomalacia occurs in grain-fed feedlot cattle.

The functions of the nervous system are directed at the maintenance of the body's spatial relation with its environment. These functions are performed by the several divisions of the nervous system including:

- The sensorimotor system, responsible for the maintenance of normal posture and gait
- The autonomic nervous system, controlling the activity of smooth muscle and endocrine glands, and thereby the internal environment of the body
- The largely sensory system of special senses
- The psychic system, which controls the animal's mental state.

The nervous system is essentially a reactive one geared to the reception of internal and external stimuli and their translation into activity and consciousness; it is dependent upon the integrity of both the afferent and efferent pathways. This integrative function makes it often difficult to determine in a sick animal whether abnormalities are present in the nervous system, the musculoskeletal system or acid–base and electrolyte status. Accordingly, the first step when examining an animal with apparent abnormalities in the nervous system is to determine whether other relevant systems are functioning normally. In this way a decision to implicate the nervous system is often made on the exclusion of other systems.

The nervous system itself is not independent of other organs and its functional capacity is regulated to a large extent by the function of other systems, particularly the cardiovascular system. Hypoxia due to cardiovascular disease commonly leads to altered cerebral function because of the dependence of the brain on an adequate oxygen supply.

It is important to distinguish between primary and secondary diseases of the nervous system since both the prognosis and the treatment will differ with the cause.

In primary disease of the nervous system the lesion is usually an anatomical one with serious, long-range consequences.

In secondary disease the lesion, at least in its early stages, is more likely to be functional and therefore more responsive to treatment, provided the defect in the primary organ can be corrected.

The clinical findings that should arouse suspicion of neurological disturbance include abnormalities in the three main functions of the system.

Posture and gait
An animal's ability to maintain a normal posture and to proceed with a normal gait depend largely upon the tone of skeletal muscle but also upon the efficiency of the postural reflexes. Abnormalities of posture and gait are among the best indications of nervous system disease because these functions are governed largely by the coordination of nervous system. Besides contributing to posture and gait, skeletal muscle tone is characteristic in its own right. However, its assessment in animals is subject to great inaccuracy because of our inability to request complete voluntary relaxation by the patient. In humans it is a very valuable index of nervous system efficiency, but in animals it has serious limitations. The most difficult step when there is a defect of gait or posture is to decide whether it originates in the skeleton, the muscles or the nerve supply.

Sensory perpectivity
Tests of sensory perception in animals can only be objective, and never subjective as they can be in humans, and any test used in animals is based heavily on the integrity of the motor system.

Mental state
Depression or enhancement of the psychic state is not difficult to judge, particularly if the animal’s owner is observant and accurate. The difficulty usually lies in deciding whether the abnormality is due to primary or secondary changes in the brain.

Principles of nervous dysfunction
Nervous tissue is limited in the ways in which it can respond to noxious influences. Because of its essentially coordinating function, the transmission of impulses along nerve fibers can be enhanced or depressed in varying degrees, the extreme degree being complete failure of transmission. Because of the structure of the system, in which nerve impulses are passed from neuron to neuron by relays at the nerve cells, there may also be excessive or decreased intrinsic activity of individual cells giving rise to an increase or decrease in nerve impulses discharged by the cells. The end result is the same whether the disturbance be one of conduction or discharge and these are the only two ways in which disease of the nervous system is manifested. Nervous dysfunction can thus be broadly divided into two forms, depressed activity and exaggerated activity. These can be further
subdivided into four common modes of nervous dysfunction: excitation (irritation) signs, release of inhibition signs, paresis or paralysis due to tissue damage, and nervous shock.

**MODES OF NERVOUS DYSFUNCTION**

**Excitation (irritation) signs**
Increased activity of the reactor organ occurs when there is an increase in the number of nerve impulses received either because of excitation of neurons or because of facilitation of passage of stimuli.

The excitation of nerve cells can be increased by many factors, including stimulant drugs, inflammation and mild degrees of those influences that in a more severe form may cause depression of excitability. Thus early or mild hypoxia may result in increased excitability while sustained or severe hypoxia will cause depression of function or even death of the neuron.

Irritation phenomena may result from many causes, including inflammation of nervous tissue associated with bacteria or viruses, certain nerve poisons, hypoxia and edema. In those diseases that cause an increase in intracranial pressure, irritation phenomena result from interference with circulation and the development of local anemic hypoxia. The major manifestations of irritation of nervous tissue are tetany, local muscle tremor, and whole body convulsions in the motor system and hyperesthesia and paresthesia in the sensory system. For the most part the signs produced fluctuate in intensity and may occur periodically as nervous energy is discharged and reaccumulated in the nerve cells.

The area of increased excitability may be local or sufficiently generalized to affect the entire body. Thus a local inflammation in the brain may cause signs of excitatory nervous dysfunction in one limb and a more extensive lesion may cause a complete convulsion.

**Release of inhibition signs**
Exaggeration of normal nervous system activity occurs when lower nervous centers are released from the inhibitory effects of higher centers. The classic example of a release mechanism is experimental decerebrate rigidity caused by transection of the brain stem between the colliculi of the midbrain. This results in an uninhibited extensor tonus of all the antigravity muscles. The head and neck are extended markedly in a posture of opisthotonos, and all four limbs in the quadruped are extended rigidly. The tonic mechanism or myotatic reflex involving the lower motor neuron has been released from the effects of the descending inhibitory upper motor neuron pathways.

Cerebellar ataxia is another example of inhibitory release. In the absence of cerebellar control combined limb movements are exaggerated in all modes of action including rate, range, force, and direction. In general, release phenomena are present constantly while the causative lesion operates, whereas excitatory phenomena fluctuate with the building up and exhaustion of energy in the nerve cells.

**Paresis or paralysis due to tissue damage**
Depression of activity can result from depression of metabolic activity of nerve cells, the terminal stage being complete paralysis when nervous tissue is destroyed. Such depression of activity may result from failure of supply of oxygen and other essential nutrients, either directly from their general absence or indirectly because of failure of the local circulation. Infection of the nerve cell itself may cause initial excitation, then depression of function and finally complete paralysis when the nerve cell dies.

Signs of paralysis are constant and are manifested by muscular paresis or paralysis when the motor system is affected and by hypoesthesia or anesthesia when the sensory system is involved. Deprivation of metabolites and impairment of function by actual invasion of nerve cells or by toxic depression of their activity produce temporary, partial depression of function that is completely lost when the neurons are destroyed.

**Nervous shock**
An acute lesion of the nervous system causes damage to nerve cells in the immediate vicinity of the lesion but there may be, in addition, a temporary cessation of function in parts of the nervous system not directly affected. The loss of function in these areas is temporary and usually persists for only a few hours. Stunting is the obvious example. Recovery from the flaccid unconsciousness of nervous shock may reveal the presence of permanent residual signs caused by the destruction of nervous tissue.

Determining the type of lesion is difficult because of the limited range of modes of reaction to injury in the nervous system. Irritation signs may be caused by bacterial or virus infection, by pressure, by vascular disturbance or general hypoxia, by poisons and by hypoglycemia. It is often impossible to determine whether the disturbance is structural or functional. Degenerative lesions produce mainly signs of paresis or paralysis but unless there are signs of local nervous tissue injury, such as facial nerve paralysis, paraplegia or local tremor, the disturbance may only be definable as a general disturbance of a part of the nervous system. Encephalopathy is an all-embracing diagnosis, but it is often impossible to go beyond it unless other clinical data, including signalment of the animal, epidemiology and systemic signs, are assessed or special tests, including radiographic examination and examination of the CSF, are undertaken.

Some information can be derived from a study of the **sign-time relationship** in the development of nervous disease. A lesion that develops suddenly tends to produce maximum disturbance of function, sometimes accompanied by nervous shock. Slowly developing lesions permit a form of compensation in that unimpaired pathways and centers may assume some of the functions of the damaged areas. Even in rapidly developing lesions partial recovery may occur in time but the emphasis is on maximum depression of function at the beginning of the disease. Thus a slowly developing tumor of the spinal cord will have a different pattern of clinical development from that resulting from an acute traumatic lesion. Another aspect of the rapidity of onset of the lesion is that irritation phenomena are more likely to occur when the onset is rapid and less common when the onset is slow.

**Clinical manifestations of disease of the nervous system**

The major clinical signs of nervous system dysfunction include:
- Altered mentation
- Involuntary movements
- Abnormal posture and gait
- Paresis or paralysis
- Altered sensation
- Blindness
- Abnormalities of the autonomic nervous system.

**ALTERED MENTATION**

Excitation states include mania, frenzy, and aggressive behavior, which are manifestations of general excitation of the cerebral cortex. The areas of the cortex that govern behavior, intellect and personality traits in humans are the frontal lobes and temporal cortex. The clinical importance of these areas, which are poorly developed in animals, is not great. The frontal lobes, temporal cortex and limbic system are highly susceptible to influences such as hypoxia and increased intracranial pressure.
Mania
In mania the animal acts in a bizarre way and appears to be unaware of its surroundings. Maniacal actions include licking, chewing of foreign material, sometimes ing. Maniacal actions include licking, chewing of foreign material, sometimes.

The animal's movements are uncontrolled and appear to be unaware of its surroundings, e.g., pigs and cattle with atlantoaxial arthroses.

Depressive states
Depressive mental states include somnolence, lassitude, narcolepsy/catalepsy, syncope and coma. They are all manifestations of depression of cerebral cortical function in various degrees and occur as a result of those influences that depress nervous system function generally as well as those that specifically affect behavior, probably via the limbic system. It is not possible to classify accurately the types of depressive abnormality and relate them to specific causes, but the common occurrences in farm animals are listed below.

Depression leading to coma
In all species this may result from:
- Encephalomyelitis and encephalomalacia
- Toxic and metabolic diseases of the brain such as uremia, hypoglycemia, hepatic insufficiency, toxemia, septicaemia and most toxins that damage tissues generally
- Hypoxia of the brain, as in peripheral circulatory failure of milk fever
- Heat stroke
- Specific poisons that cause somnolence, including bromides, Amitraz in horses, methyl alcohol, Filix mas (male fern), kikuyu grass.

Syncope
The sudden onset of fainting (syncope) may occur as a result of:
- Acute circulatory and heart failure leading to acute cerebral hypoxia
- Spontaneous cerebral hemorrhage, a most unlikely event in adult animals
- Traumatic concussion and contusion
- Lightning stroke, electrocution.

Narcolepsy (cataplexy)
Affected animals experience episodes of uncontrollable sleep and literally "fall asleep." The disease is recorded in Shetland ponies and is thought to be inherited in them, in other horses, and in cattle.5

Compulsive walking or headpressing
Headpressing is a syndrome characterized by the animal pushing its head against fixed objects, into a corner of a pen, leaning into a stanchion or between fence posts. Headpressing should be differentiated from compulsive walking, where affected animals put their heads down and walk slowly while appearing blind. If they walk into an object they lean forward and indulge in headpressing; if confined to a stall they will often walk around the pen continuously or headpress into a corner. The syndrome represents a change in behavior pattern due to an unsatisfied compulsive drive characteristic of a disorder of the limbic system. Causes include:
- Toxic and metabolic brain disease, especially polyencephalomalacia and hepatic encephalopathy
- Diseases manifested by increased intracranial pressure
- Encephalomyelitides.

Airless wandering
A similar but less severe syndrome to compulsive walking is aimless walking, severe mental depression, apparent blindness, with tongue protrusion and continuous chewing movements, although the animal is unable to ingest feed or drink water. Causes include:
- Toxic and metabolic diseases of brain, including poisoning by Helichrysum sp. and tansy mustard
- Degenerative brain diseases, e.g. nigropallidal encephalomalacia in horses, ceroid lipofuscinosis in sheep, hydrocephalus in the newborn.

INHOLUNTARY MOVEMENTS
Involuntary movements are due to involuntary muscle contractions, which include gradations from fasciculations, shivering, tremor, to tetany, seizures or convulsions. Opisthotonos or "backward tone" is a sustained spasm of the neck and limb muscles resulting in dorsal and caudal extension of the head and neck with rigid extension of the limbs.

Tremor
This is a continuous, repetitive twitching of skeletal muscles, which is usually visible and palpable. The muscle units involved may be small and cause only local skin movement, in which case the tremor is described as fasciculations; or the muscle units may be extensive, the movement much coarser and sufficient to move the extremities, eyes or parts of the trunk. The tremor may become intensified when the animal undertakes some positive action, this usually being indicative of cerebellar involvement and is the counterpart of intention tremor in humans. True tremor is often sufficiently severe to cause incoordination and severe disability in gait. Examples of causes of tremor include:
- Diffuse diseases of the cerebrum, cerebellum, spinal cord
- Degenerative nervous system disease, e.g. hypomyelinosgenesis of the
newborn as in congenital tremor of pigs and calves, poisoning by Swainsona sp.
- Toxic nervous system disease caused by a large number of poisons, especially poisonous plants and fungi, *Clostridium botulinum* toxin in shaker foal syndrome; metabolic disease such as hyperkalemic periodic paralysis in the horse; early stages of hypocalcemia in the cow (fasciculations of the eyelids and ears).

**Tics**
Tics are spasmodic twitching movements made at much longer intervals than in tremor, the intervals being usually at least several seconds in duration and often much longer. The movements are sufficiently widespread to be easily visible and are caused by muscles that are ordinarily under voluntary control. They are rare in large animals but may occur after traumatic injury to a spinal nerve.

**Tetany**
Tetanus is a sustained contraction of muscles without tremor. The most common cause is *Clostridium tetani* intoxication following localized infection with the organism. The degree of muscular contraction can be exaggerated by stimulation of the affected animal and the limbs are rigid and cannot be passively flexed easily—‘lead pipe’ rigidity.

**Myoclonus** is a brief, intermittent tetanic contraction of the skeletal muscles that results in the entire body being rigid for several seconds, followed by relaxation. Inherited congenital myoclonus (hereditary neuraxial edema) of Polled, Horned and crossbred Hereford calves is a typical example. Affected calves are bright and alert and can suck normally but if they undertake a voluntary movement or are handled, their entire body becomes rigid for 10–15 seconds.

**Convulsions**
Convulsions, seizures, fits, or ictus are violent muscular contractions affecting part or all of the body and occurring for relatively short periods as a rule, although in the late stages of encephalitis they may recur with such rapidity as to give the impression of being continuous.

Convulsions are the result of abnormal electrical discharges in forebrain neurons that reach the somatic and visceral motor areas and initiate spontaneous, paroxysmal, involuntary movements. These cerebral dysrhythmias tend to begin and end abruptly and they have a finite duration. A typical convulsion may have a prodromal phase or aura that lasts for minutes to hours, during which the animal is oblivious to its environment and seems restless. The beginning of the convulsion may be manifested as a localized partial convulsion of one part of the body that soon spreads to involve the whole body, when the animal usually falls to the ground thrashing rhythmically. Following the convulsion there may be depression and temporary blindness, which may last for several minutes up to a few hours.

The convulsion may be clonic, the typical ‘padding’ involuntary movement in which repeated muscle spasms alternate with periods of relaxation. Tetanic or tonic convulsions are less common and are manifested by prolonged muscular spasm without intervening periods of relaxation. True tetanic convulsions occur only rarely, chiefly in strychnine poisoning and in tetanus, and in most cases they are a brief introduction to a clonic convulsion.

Convulsions can originate from disturbances anywhere in the prosencephalon, including cerebrum, thalamus or even the hypothalamus alone. However, the initiating cause may be in the nervous system outside the cranium or in some other system altogether, so that convulsions are therefore often subdivided into intracranial and extracranial types. Causes are many and include the following.

- **Intracranial convulsions** are caused by:
  - Encephalomyelitis, meningitis
  - Encephalomalacia
  - Acute brain edema
  - Brain ischemia, including increased intracranial pressure
  - Local lesions caused by trauma (concussion, contusion), abscess, tumor, parasitic injury, hemorrhage
  - Inherited idiopathic epilepsy.

**Extracranial convulsions** are caused by brain hypoxia, as in acute circulatory or cardiac failure, and toxic and metabolic diseases of the nervous system, including:
- Hepatic encephalopathy
- Hypoglycemia (as in newborn piglets and in hyperinsulinism due to islet cell adenoma of the pancreas as described in a pony)
- Hypomagnesemia (as in lactation tetany in cows and mares)
- Inorganic poisons, poisonous plants and fungi. There are too many to give a complete list but well-known examples are the chlorinated hydrocarbons, plutonics used in bloat control in cattle, *Clostridium* spp. intoxications, e.g. *Clostridium perfringens* type D and *Clostridium sordelli*, and subacute fluoracetate poisoning
- Congenital and inherited defects without lesions, e.g. familial convulsions and ataxia in Angus cattle.

**Involuntary spastic paresis**
Involuntary, intermittent contractions of large muscle masses may result in spasmodic movements of individual limbs or parts of the body. In most, contractions occur when voluntary movement is attempted. Diseases in this category are:
- Stringhalt and Australian stringhalt of horses
- Inherited spastic paresis (Elso-heel) of cattle
- Inherited periodic spasticity (stall-crank) of cattle
- Inherited congenital myotonia of cattle
- Inherited myotonia of goats.

**ABNORMAL POSTURE AND GAIT**

**Posture**
Posture is evaluated with the animal at rest. Abnormal postures may be adopted intermittently by animals in pain but in diseases of the nervous system the abnormality is usually continuous and repeatable. Deviation of the head and neck from the axial plane or rotation of the head and neck from the horizontal plane (head tilt) and drooping of the lips, eyelids, cheeks and ears, and opisthotonos and orthotonos are examples, although the latter two are often intermittent in that they occur as part of a convulsive seizure. Head pressing and assumption of a dog-sitting posture are further examples. Abnormalities of posture and gait are the result of lesions of the brainstem, cerebellum, all levels of the spinal cord, spinal nerve roots, peripheral nerves, neuromuscular junctions and muscles. The clinical emphasis is on vestibular disease, cerebellar disease and spinal cord disease. It is important to recognize that cerebral lesions do not cause abnormalities in posture and gait.

**Vestibular disease**
The vestibular system is a special proprioceptive system that assists the animal to maintain orientation in its environment with respect to gravity. The system helps to maintain the position of the eyes, trunk and limbs in relationship to movements and positioning of the head.

From the vestibular nuclei, the vestibulospinal tracts descend ipsilaterally through the length of the spinal cord. These neurons are facilitatory to ipsilateral motor neurons going to extensor muscles of the limbs, are inhibitory to ipsilateral motor flexor muscles and are inhibitory to contralateral extensor muscles. The principal effect of unilateral stimulation of this system on the limbs is a relative ipsilateral extensor tonus and contralateral flexor tonus, which promotes ipsilateral support of the trunk against gravity. Conversely, a unilateral vestibular lesion usually results in ipsilateral...
flexor and contralateral extensor tonus, forcing the animal toward the side of the lesion.

The nuclei of cranial nerves III, IV, and VI, which control eye movement, are connected with the vestibular system by way of a brainstem tract — the medial longitudinal fasciculus. Through this tract, coordinated eye movements occur with changes in positioning of the head. Through these various pathways, the vestibular system coordinates movements of the eye, trunk, and limbs with head movements and maintains equilibrium of the entire body during motion and rest.

Signs of vestibular disease vary depending on whether there is unilateral or bilateral involvement and whether the disease involves peripheral or central components of the system.

The vestibular influence on balance can be affected:

- At the inner ear
- Along the vestibular nerve or
- At the vestibular nucleus in the medulla.

Unilateral excitation or loss of function can be caused by lesions at any of these points.

General signs of vestibular system dysfunction are staggering, leaning, rolling, circling, drifting sideways when walking and a head tilt, and various changes in eye position such as strabismus and nystagmus. The walking in a circle toward the affected side is accompanied by increased tone in the contralateral limbs, which is most easily observed in the contralateral forelimb. Rotation or tilt of the head occurs and severely affected animals fall to the affected side.

When the lesion affects the inner ear, as it may do in otitis media, the affected side is turned down, the animal falls to that side and there may be facial paralysis on the same side if the lesion is extensive and affects the seventh cranial nerve. In the recumbent position, the affected side is held to the ground, and if these animals are rolled over to the opposite side they quickly roll back to the affected side. When the vestibular nuclei are affected, which may occur in listeriosis, the animal falls to the affected side.

Nystagmus and forced circling are common when there is irritation of the vestibular nucleus or the medial longitudinal fasciculus.

**Causes of vestibular disease include:**

- Otitis media–interna with involvement of the inner ear
- Focal lesion at the vestibular nucleus, e.g. listeriosis
- Traumatic injury to the vestibular apparatus in the horse caused by fracture of the basisphenoid, basioccipital and temporal bones in a traumatic injury. The clinical signs include lack of control of balance, rotation of the head, circling to the affected side, nystagmus and facial paralysis.

**In paradoxical vestibular syndrome** there is also head tilting, but circling in a direction away from the side of the lesion. Deviation of the head and neck must be distinguished from a head tilt. Asymmetric lesions of the forebrain such as a brain abscess, some cases of polioencephalomalacia, verminous larval migration or head trauma may cause an animal to hold its head and neck turned to one side, but there is no head tilt and the circle is large in diameter. In fact, the presence of a head tilt (deviation of eyes away from a horizontal plane) accompanied by a tight circle provides clinically useful methods of differentiating a cerebral lesion from a vestibular lesion.

**Gait**

Gait is assessed when the animal is moving. Neurological gait abnormalities have two components, **weakness** and **ataxia**. Weakness (paresis) is evident when an animal drags its limbs, has worn hooves or has a low arc to the swing phase of the stride. When an animal bears weight on a weak limb, the limb often trembles and the animal may even collapse on that limb because of lack of support. While circling, walking on a slope, and walking with the head elevated, an animal frequently will stumble on a weak limb and knuckle over at the fetlock. During manipulation of the limb, the veterinarian will usually make the subjective observation that the muscle tone is reduced.

**Ataxia** Ataxia is an unconscious, general proprioceptive deficit causing incoordination when the animal moves. Ataxia is manifest as a swaying from side to side of the pelvis, trunk and sometimes the whole body (truncal sway). Ataxia may also appear as a weaving of the affected limb during the swing phase of the stride. This often results in abducted or adducted foot placement, crossing of the limbs or stepping on the opposite foot.

**Hypermotia** is an increased range of movement and is seen as an over-reaching of the limbs with excessive joint movement. Hypermotia without paresis is characteristic of spinocerebellar and cerebellar disease.

**Hypometria** is a decreased range of movement that is characterized by a stiff or spastic movement of the limbs with little flexion of the joints, particularly the carpals and tarsal joints.

**Dysmetria** is a term that includes both hypermetria and hypometria, with goose-stepping being the most common sign of dysmetria. Dysmetria usually is caused by a lesion in the cerebellum or cerebellar pathway.

In equine degenerative myeloneuropathy, there is dysmetria of the hindlimbs and tetraparesis due to neuraxonal dystrophy originating in the accessory cuneate nuclei. Severely affected horses lift their feet excessively high and stamp them to the ground.

**Cerebellar disease**

When cerebellar function is abnormal, there is ataxia, which is an incoordination when the animal moves. In general terms there are defects in the rate, range and direction of movement. In typical cerebellar diseases, ataxia of the limbs is common and no weakness is evident. In true cerebellar ataxia (e.g. cerebellar hypoplasia) the affected animal stands with the legs wide apart, sways and has a tendency to fall. Ataxia of the head and neck are characterized by wide, swinging, head excursions, jerky head bobbing and an intention tremor (nodding) of the head.

The head tremor may be the most obvious sign in mild cases of cerebellar hypoplasia in young foals. The limbs do not move in unison, the movements are grossly exaggerated, muscular strength is usually preserved and there is a lack of proper placement of the feet (hypermetria and hypometria), so that falling is common. The fault in placement is the result of poor motor coordination and not related in any way to muscle weakness or proprioceptive deficit. Attempts to proceed to a particular point are usually unsuccessful and the animal cannot accurately reach its feed or drinking bowl. Examples of cerebellar disease include:

- Inherited defects of cerebellar structure or abiotrophy in most breeds of cattle and in Arabian horses
- Congenital cerebellar defects resulting from maternal viral infections such as bovine virus diarrhea (BVD) infection in cattle
- Dysplastic disease of the cerebellum of the horse
- Traumatic injury, e.g. by parasite larvae such as Hyoderma bovis, which have caused unilateral cerebellar ataxia in adult cattle
- Tremorogenic mycotoxins and ryegrasses
- Encephalomyelitis in which other localizing signs also occur.

**Spinal cord disease**

Ataxia due to cerebellar dysfunction can be difficult to differentiate from the proprioceptive defects and partial motor
paralysis (weakness) that occur in animals with spinal cord lesions and it is most important that this differentiation be made. Spinal cord disease, causing varying degrees of weakness, and ataxia are common in large animals. The weakness is caused by damage to the upper or lower motor neurons and the proprioceptive deficit by damage to the ascending sensory neurons. With a mild or even moderate cervical spinal cord lesion in an adult cow or horse, signs of ataxia and weakness may be evident in the pelvic limbs only and it can be difficult to determine whether the thoracic limbs are involved.

Close examination of the gait, posture and postural reactions in the limbs, together with a search for localizing abnormalities, will often be productive in localizing the lesion. Signs of weakness or ataxia may be elicited by gently pushing the hindquarters to one side or pulling the tail to one side as the animal is walked (the sway response). The normal animal resists these movements or steps briskly to the side as it is pushed or pulled. The weak animal can be easily pulled to one side and may stumble or fall. The weak animal may also tend to buckle or collapse when strong pressure is applied with the hand over the withers and loin regions. The ataxic animal may sway to one side, be slow to protract a limb, cross its hindlegs or step on its opposite limb.

It is often difficult to distinguish paresis from ataxia but in most instances it is unimportant because of the close anatomical relationship of the ascending general proprioceptive and descending upper motor neuron tracts in the white matter of the spinal cord. These same abnormal sway responses can be elicited in the standing animal.

The ataxic animal may abduct the outside pelvic limb too far as it is pushed to one side or moved in a small circle. This may appear as a hypermetric movement similar to a stringhalt action and is assumed to be a sign of a general proprioceptive tract lesion. The pushed or circled animal may keep a clinically affected pelvic limb planted in one position on the ground and pivot around it without moving it. The same failure to protract the limb may be seen on backing. It may even force the animal into a ‘dog-sitting’ posture.

Examples of ataxia due to spinal cord disease include:
- Limited trauma to the spinal cord
- The early stages of a developing compression lesion in the vertebral canal
- Degenerative and inflammatory diseases of the nervous system, especially those causing enzootic incoordination in horses and staggerers in sheep (both of them dealt with under their respective headings)
- Functional diseases in toxic and metabolic diseases of the nervous system in which lesions have not yet been identified and caused mainly by poisons, especially plant materials.
- Typical examples are poisoning by the fungi: *Claviceps* *paspali, Diplodia* spp., *Acremonium lilii*, the grass *Phalaris aquatica*, the ferns *Zamia* and *Xanthorrhoea* spp. and herbaceous plants such as *Kallstroemia, Vicia, Baccharis, Solanum, Aesculus* and *Ficus* spp.
- Nutritional deficiency especially of thiamin, occurring naturally in horses poisoned by branken and horsetail, and experimentally in pigs
- Developmental defects including congenital abnormalities and abortifacient abnormalities that develop some time after birth. Examples are Brown Swiss weavers and Pietrain pig creepers.

In many of these diseases incoordination and paresis are a stage in the development of tetraplegia or paraplegia.

**PARESIS AND PARALYSIS**

The motor system comprises:
- The pyramidal tracts, which originate in the motor cortex
- The extrapyramidal system, which originates in the corpus striatum, red nucleus, vestibular nucleus and roof of the midbrain
- The peripheral nerves, which originate in the ventral horn cells.

The pyramidal tracts are of minor importance in hoofed animals (ungulates), reaching only to the fourth cervical segment. Accordingly, lesions of the motor cortex in farm animals do not produce any deficit of gait. Neither is there any paresis, although in an acute lesion weakness may be evident for the first day or two. If the lesion is unilateral the paresis will be on the contralateral side. This is in marked contrast to the severe abnormalities of posture and gait that occur with lesions of the pons, medulla, and spinal cord.

The main motor nuclei in these animals are subcortical and comprise the extrapyramidal system, and most combined movements are controlled by nerve stimuli originating in the tectal nuclei, reticular nuclei, vestibular nuclei and possibly red nuclei. The pyramidal and extrapyramidal tracts comprise the upper motor neurons, which reach to the ventral horn cells of the spinal cord, which cells together with their peripheral axons form the lower motor neurons. Paralysis is a physiological end result in all cases of motor nerve injury, which if severe enough is expressed clinically. The type of paralysis is often indicative of the site of the lesion.

A lesion of the upper motor neuron causes:
- Spasticity with loss of voluntary movement
- Increased tone of limb muscles
- Increased spinal reflexes.

The spasticity of an upper motor neuron lesion usually occurs with the affected limb in extension. These are all release phenomena resulting from liberation of spinal reflex arcs from higher control.

A lesion of the lower motor neuron causes:
- Paresis or paralysis with loss of voluntary movement
- Decreased tone of the limb muscles
- Absence of spinal reflexes
- Wasting of the affected muscle (neurogenic atrophy).

As injuries to specific peripheral nerves are treated surgically, these are dealt with in surgical textbooks and are not repeated here.

A special form of paralysis is the Schiff-Sherrington syndrome, which is common in dogs but recorded rarely in large animals. It is caused by acute, severe, compressive injury of the thoracolumbar spinal cord and manifested by extensor rigidity or hypertonia of the forelimbs and hypotonic paralysis of the hindlimbs. Neurons located in the lumbar spinal cord are responsible for the tonic inhibition of extensor muscle alpha motor neurons in the cervical intumescence. The cell bodies of these neurons are located in the ventral gray column from L1-L7, with a maximum population from L2-L4. Their axons ascend to the cervical intumescence. Acute severe lesions cranial to these neurons and caudal to the cervical intumescence will suddenly deprive the cervical intumescence neurons of this source of tonic inhibition, resulting in a release of these latter neurons. This results in extensor hypertonia observed in the thoracic limbs which can function normally in the gait and postural reactions, except for the hypotonia.

The degree of paresis or paralysis needs to be defined. Paralysis is identified as an inability to make purposeful movements. Thus convulsive, uncontrolled movements as they occur in polioencephalomalacia may still fit a description of paralysis. Paresis, or weakness short of paralysis, can be classified into four categories.
- Animals that cannot rise, nor support themselves if helped up, but can make purposeful movements in attempting to rise
- Animals that cannot rise but can support themselves if helped up
- Animals that can rise but are parietic and can move the limbs well and stumble only slightly on walking
- Animals that move with difficulty and have severe incoordination and stumbling.

Probably the most difficult decision in farm animal neurology is whether a patient’s inability to move is because of a nervous or muscular deficit. For example, the horse recumbent because of exertional rhabdomyolysis often resembles a horse with an injured spinal cord. Examples of paresis and paralysis include:

- **Focal inflammatory, neoplastic, traumatic lesions in the motor pathway.** These lesions usually produce an asymmetric nervous deficit
- **Toxic and metabolic diseases** of the nervous system in their most severe form, e.g. flaccid paralysis associated with tickbite (*Ixodes* holocyclus, *Ornithodoros* sp.), poisoning, botulism, snakebite. Comparable tetanic paralyses include tetanus, lactation tetany of mares, hypomagnesemic tetany of cows and calves. In contrast to inflammatory, neoplastic and traumatic lesions in the motor pathway, toxic and metabolic lesions usually produce a symmetric nervous deficit.

**Neurogenic muscular atrophy**

Destruction of the lower motor neurons either within the vertebral canal or peripheral to it causes neurogenic atrophy. Whether or not the atrophy is visible depends on how many neurons and therefore how many muscle fibers are affected.

**ALTERED SENSATION**

Lesions of the sensory system are rarely diagnosed in animals, except for those affecting sight and the vestibular apparatus, because of the impossibility of measuring subjective responses.

Thus, although animals must experience paresthesia, as in Aujeszky’s disease (pseudorabies) in cattle and sheep, the animal’s response of licking or scratching does not make it possible to decide whether the diagnosis should be paresthesia or pruritus. Lesions of the peripheral sensory neurons cause hypersensitivity or decreased sensitivity of the area supplied by the nerve. Lesions of the spinal cord may affect only motor or only sensory fiber tracts or both, or may be unilateral.

Although it is often difficult to decide whether failure to respond to a normally painful stimulus is due to failure to perceive or inability to respond, certain tests may give valuable information. For example, the test commonly used is pricking the skin with a needle, or pinching the skin with a pair of forceps, and observing the reaction. In exceptional circumstances light stroking may elicit an exaggerated response. The ‘nibbling’ reaction stimulated by stroking the lumbar back of sheep affected with scrapie is a striking example of hypersensitivity.

In every test of sensitivity it must be remembered that there is considerable variation between animals and in an individual animal from time to time, and much discretion must be exercised when assessing the response. In any animal there are also cutaneous areas that are more sensitive than others. The face and the cranial cervical region are highly sensitive, the caudal cervical and shoulder regions less so, with sensitivity increasing over the caudal thorax and lumbar region to a high degree on the perineum. The proximal parts of the limbs are much less sensitive than the distal parts and sensitivity is highest over the digits, particularly on the medial aspect.

**Absence of a response** to the application of a painful stimulus to the limbs (absence of the withdrawal reflex) indicates interruption of the reflex arc. Absence of the reflex with persistence of central perception, as demonstrated by groaning or body movement such as looking at the site of stimulation application, indicates interruption of motor pathways and that central perception of pain persists. In the horse the response can be much more subtle than in other species, with movements of the ears and eyelids being the best indicators of pain perception. Increased sensitivity is described as **hypercotesthesia** or so-called **hyposthesia** and complete absence of sensitivity is described as **anesthesia**. Special cutaneous reflexes include the anal reflex, in which spasmoid contraction of the anus occurs when it is touched, and the corneal reflex, in which there is closure of the eyelids on touching the cornea. The (cutaneous) trunci panniculus reflex is valuable in that the sensory pathways, detected by the prick of a pin, enter the cord at spinal cord segments T1–L3, but the motor pathways leave the cord only at spinal cord segments C8, T1, T2. The quick twitch of the superficial cutaneous muscle along the whole back, which is the positive response (panniculus reflex), is quite unmistakable. Examination of the eye reflexes and hearing are discussed under examination of the cranial nerves (see below).

**BLINDNESS**

Blindness is manifested as a clinical abnormality by the animal walking into objects that it should avoid. The menace or blink reflex is used to test the visual pathway. A threatening gesture of the hand (or even better by the index finger in a pointing manner) toward the eye elicits immediate closure of the eyelids. The hand must come close enough to the eye without touching the tactile hairs of the eyelids or creating a wind which can be felt by the animal. Some stoic, depressed or even excited animals may not respond to a menace reflex with closure of the eyelids; others may keep the eyelids partially or almost closed. It may be necessary to alert the patient to the risk of injury by touching the eyelids first. The menace reflex is a learned reflex that is absent in neonates.

The most definitive test is to make the animal walk an obstacle course and place objects in front of it so that it must step over the objects easily. A similar procedure is the only way to test for **night blindness** (nyctalopia). The area should be dimly lit but the observer should be able to see the obstructions clearly. A decision that the animal is blind creates a need for examination of the visual pathways.

**Central or peripheral blindness**

Blindness may be central or peripheral. Animals with forebrain lesions are centrally blind, with depressed menace response in one or both eyes while the pupillary light reflexes are commonly intact. In peripheral blindness, such as hypovitaminosis-A, the menace reflex is absent, and the pupillary light reflexes are also absent.

Blindness can be caused by lesions along the visual pathway, from the eye to the cerebral cortex:

- **Diseases of the orbit** including keratoconjunctivitis, hypopyon, cataract, panophthalmitis, mixed ocular defects inherited in white Shorthorn and Jersey cattle, night blindness in Appaloosa horses, sporadic cases of blindness due to idiopathic retinal degenerative disease in cattle
- **Diseases of the retina** including retinal dysplasia of goats, lenticular cataracts caused by poisoning with hygromycin in pigs, congenital ocular malformations in calves after intrauterine infection with BVD virus (usually accompanied by cerebellar defects)
- **Diseases of the optic nerve and chiasma**, e.g. abscess of pituitary rete mirabile, constriction of optic nerve by diet deficient in vitamin A. Tumor of pituitary gland, injury to the optic
nerve, especially in horses after rearing and falling backwards. There is a sudden onset of unilateral or bilateral blindness with no ophthalmological change until 3–4 weeks after the injury, when the optic disc becomes paler and less vascular.

- Metabolic or ischemic lesions of the cerebral cortex as in polioencephalomalacia, cerebral edema, hydrocephalus
- Localized infectious or parasitic lesions caused by abscesses, migrating larvae
- Functional blindness in which there is complete, often temporary, blindness in the absence of any physical lesions. Causes are acetonemia, pregnancy toxemia and acute carbohydrate indigestion (hyper D-lactatemia) of ruminants
- Specific poisonings causing blindness include *Felix mas* (male fern), *Cheilanthes* spp. (rockfern) and rape. *Stypandra* spp. cause a specific degeneration of the optic nerves. Lead poisoning in cattle.

**ABNORMALITIES OF THE AUTONOMIC NERVOUS SYSTEM**

Lesions affecting the cranial parasympathetic outflow do so by involvement of the oculomotor, facial, vagus, and glossopharyngeal nerves or their nuclei and the effects produced are discussed under examination of the individual nerves.

In general, the lesions cause abnormality of pupillary constriction, salivation and involuntary muscular activity in the upper part of the alimentary and respiratory tracts. Lesions of the spinal sympathetic system interfere with normal function of the heart and alimentary tract. For the most part, affections of the autonomic nervous system are of minor importance in farm animals. Central lesions of the hypothalamus can cause abnormalities of heat exchange, manifested as neurogenic hyperthermia or hypothermia and obesity, but they are also of minor importance.

Some manifestations of autonomic disease are important. Autonomic imbalance is usually described as the physiological basis for spasmodic colic of horses; grass sickness of horses is characterized by degenerative lesions in the sympathetic ganglia; involvement of the vagus nerve in traumatic reticuloperitonitis of cattle can lead to impaired forestomach and abomasal motility and the development of vagus indigestion.

Defects of sphincter control and motility of the bladder and rectum may also be of importance in the diagnosis of defects of the sacral parasympathetic outflow and the spinal sympathetic system. The sacral segments of the spinal cord are the critical ones, and loss of their function will cause incontinence of urine and loss of rectal tone. The parasympathetic nerve supply to the bladder stimulates the detrusor muscle and relaxes the sphincter; the sympathetic nerve supply has the reverse function. A spinal cord lesion may cause loss of the parasympathetic control and result in urinary retention. Incontinence, if it occurs, does so from overflow. When the sympathetic control is removed incontinence occurs but the bladder should empty. Similar disturbances of defecation occur. Both micturition and defecation are controlled by medullary and spinal centers but some measure of control is regained even when the extrinsic nerve supply to the bladder and rectum is completely removed.

**Special examination of the nervous system**

Veterinarians commonly include several components of a neurological examination in a complete clinical examination. Most often a diagnosis and differential diagnosis can be made from consideration of the history and the clinical findings. However, if the diagnosis is uncertain it may be necessary to conduct a complete neurological examination, which may uncover additional clinical findings necessary to make a diagnosis and give a prognosis.

The accuracy of clinical diagnosis of neurological diseases in the horse is high. In a study of 210 horses in which a definitive pathological diagnosis was confirmed, the overall accuracy of clinical diagnosis for all diseases was 95%; the accuracy ranged from 0.79–1.00, the sensitivity varied from 0.73–0.95 and the specificity varied from 0.88–1.00 for individual disease categories. Some neurological diseases are therefore underdiagnosed while others are overdiagnosed. The use of careful and thorough clinical examinations and diagnostic techniques, combined with confirmed pathological diagnoses, will result in more accurate diagnosis and therapy. Retrospective studies of series of ataxic horses, for example, will add to the body of knowledge and improve diagnosis.

**THE NEUROLOGICAL EXAMINATION**

The primary aim of the neurological examination is to confirm whether or not a neurological abnormality exists and to determine the neuroanatomical location of the lesion. A clinicoanatomical diagnosis is necessary before one can develop a list of differential diagnoses and decided whether or not treatment is possible. The format for a precise practical examination procedure that is logical in sequence, easy to remember with practice, and emphasizes the need for an anatomical diagnosis is outlined below. The rationale for the sequence is that the examination starts from a distance to assess posture and mentation, and then proceeds to a closer examination that may require placing the animal in stocks or a chute. The examination sequence is therefore suitable for minimally handled beef cattle, dairy cattle, horses, sheep, goats, and New World camels. The results of the neurological examination should be documented and not left to memory. There are many standard examination forms available that outline each step in the examination and provide for documentation of the results.

**SIGNALMENT AND EPIDEMIOLOGY**

The age, breed, sex, use, and value of the animal are all important considerations in the diagnosis and prognosis of neurological disease. Some diseases occur more frequently under certain conditions: for example, lead poisoning in nursing beef calves turned out to pasture in the spring of the year. *Histophilus somni* meningoencephalitis occurs most commonly in feedlot cattle from 6–10 months of age and hypovitaminosis A occurs most commonly in beef calves 6–8 months of age after grazing dry summer pastures. In the horse there are several clearly defined diseases that affect the spinal cord including cervical stenotic myelopathy, degenerative myeloneuropathy, protozoal myelitis, equine rhinopneumonitis myelopathy, rabies poliomecephalomyelitis and equine motor neuron disease. Some of these diseases have distinguishing epidemiological characteristics that are useful in diagnosis and differential diagnosis. The neurological examination of the newborn foal is fraught with hazards because of the different responses elicited from those in adults. The differences relate mostly to the temporary dysmetria of gait and exaggerated responses of reflexes.

**HISTORY**

Special attention should be given to the recording of an accurate history. The questioning of the owner should focus on the primary complaint and when it occurred and how it has changed over time (the time–sign relationship). The duration of signs, the mode of onset, particularly whether acute with later
When the disease is a herd problem the owner should be questioned about the description of signs that occur only intermittently should be ascertained. When the disease is a herd problem the morbidity and mortality rates and the method of spread may indicate an intoxication when all affected animals show signs within a very short period. Diseases associated with infectious agents may have an acute or chronic onset. Neoplastic diseases of the nervous system may begin abruptly but are often slowly progressive. For some diseases, such as epilepsy, consideration of the history may be the only method of making a diagnosis. Traumatic injuries have a sudden onset and then often stabilize or improve.

When obtaining a history of convulsive episodes an estimate should be made of their duration and frequency. The pattern is also of importance, and may be diagnostic, e.g., in salt poisoning in swine. The occurrence of pallor or cyanosis during the convulsion is of particular importance in the differentiation of cardiac syncope and a convulsion originating in the nervous system.

HEAD

Behavior

The owner should be questioned about the animal’s abnormal behavior, which can include bellowing, yawning, licking, mania, convulsions, aggressiveness, headpressing, wandering, compulsive walking and head-shaking. Head-shaking may be photic in origin and can be tested by the application of blindfolds, covering the eyes with a face mask and observing the horse in total darkness outdoors. In one horse, head-shaking ceased with blindfolding or night darkness outdoors, and became less with the use of gray lenses. Outdoor behavior suggested efforts to avoid light.

Mental status

Assessment of mental status is based on the animal’s level of awareness or consciousness. Coma is a state of complete unresponsiveness to noxious stimuli. Other abnormal mental states include stupor, somnolence, deliriousness, lethargy and depression. Large animals that are recumbent because of spinal cord disease are commonly bright and alert unless affected with complications, which may cause fever and anorexia. Mature cattle that are recumbent with a spinal cord lesion and not used to being handled may be quite aggressive and apprehensive.

Head position and coordination

Lesions of the vestibular system often result in a head tilt. Lesions of the cerebrum often result in deviation of the head and neck. In cerebellar disease, there may be jerky movements of the head, which are exaggerated by increasing voluntary effort. These fine jerky movements of the head are called intention tremors. Animals with severe neck pain will hold their neck in a fixed position and be reluctant to move the head and neck. Head-shaking in horses has been associated with ear mite infestation, otitis externa, cranial nerve dysfunction, cervical injury, ocular disease, guttural pouch mycosis, dental periapical osteitis and vasomotor rhinitis. However, idiopathic head-shaking in the horse is often associated with evidence of nasal irritation, sneezing and snorting, nasal discharge, coughing and excessive lacrimation.

Cranial nerves

Abnormalities of cranial nerve (CN) function assist in localizing a lesion near or within the brainstem. Some of the information on cranial nerve dysfunction is presented in tabular form (Tables 12.1–12.6) in addition to the more detailed examination described here.

Olfactory nerve (CN I)

Tests of smell are unsatisfactory in large animals because of their response to food by sight and sound.

Optic nerve (CN II)

The only tests of visual acuity applicable in animals are testing the eye preservation (menace) reflex, provoking closure of the eyelids; and withdrawal of the head by stabbing the finger at the eye; and by making the animal run a contrived obstacle course. Both tests are often difficult to interpret and must be carried out in such a way that other senses are not used to determine the presence of the obstacles or threatened injury. In more intelligent species, a good test is to drop some light object such as a handkerchief or feather in front of the animal. It should gaze at the object while it is falling and continue to watch it on the ground. The same method can be applied to young ruminants, which demonstrate normal vision by following the examiner’s moving hand at an age so early that they have not yet developed a

Table 12.1 Correlation between clinical findings and location of lesions in the nervous system of some common diseases of mental status (Behavior)
This nerve supplies the pupilloconstrictor muscles of the iris and all the extrinsic muscles of the eyeball except the dorsal oblique, the lateral rectus and the retractor muscles. Loss of function of the nerve results in pupillary dilatation and defective pupillary constriction when the light intensity is increased, abnormal position (ventrolateral deviation) or defective movement of the eyeballs and palpebral ptosis.

The pupillary light reflex is best tested by shining a bright point source of light into the eye, which causes constriction of the iris of that eye (direct pupillary reflex). Constriction of the opposite eye (consensual pupillary light reflex) will also occur. The consensual light reflex may be used to localize lesions of the optic pathways.

Examination of the menace reflex (eye preservation reflex to a menace) and the results of the pupillary light reflex can be used to distinguish between blindness due to a lesion in the cerebral cortex (central blindness) and that due to lesions in the optic nerve or other peripheral parts of the optic pathways (peripheral blindness).

As examples, in polioencephalomalacia (central blindness) the menace reflex is absent but the pupillary light reflex is present. In the ocular form of hypovitaminosis A (peripheral blindness) in cattle the menace reflex is also absent, the pupils are widely dilated and the pupillary light reflex is absent. In polioencephalomalacia, the optic nerve, oculomotor nucleus and oculomotor nerve are usually intact but the visual cortex is not; in hypovitaminosis A the optic nerve is usually degenerate, which interferes with both the menace and pupillary light reflexes.

**Testing** of ocular movements can be carried out by moving the hand about in front of the face. In paralysis of the oculomotor nerve there may also be deviation from the normal ocular axes and rotation of the eyeball. There will be an absence of the normal horizontal nystagmus reaction with a medial jerk of the eyeball in response to quick passive movement of the head. Failure to jerk laterally indicates a defect of the abducens nerve.

**Trochlear nerve (CN IV)**

This nerve supplies only the dorsal oblique muscle of the eye so that external movements and position of the eyeball are abnormal (dorsolateral fixation) when the nerve is injured. This is common in polioencephalomalacia in cattle, resulting in a dorsomedial fixation of the eyeball. In other words, the medial angle of the pupil is displaced dorsally when the head is held in normal extension.

**Trigeminal nerve (CN V)**

The sensory part of the trigeminal nerve supplies sensory fibers to the face and can be examined by testing the palpebral reflex and the sensitivity of the face. The motor part of the nerve supplies the muscles of mastication and observation of the act of chewing may reveal abnormal jaw movements and asymmetry of muscle contractions. There may also be atrophy of the muscles, which is best observed when the lesion is unilateral.

**Abducence nerve (CN VI)**

Because the abducence nerve supplies motor fibers to the retractor and lateral rectus muscles of the eyeball, injury to the nerve may result in protrusion and medial deviation of the globe. This is not readily observable clinically. An inherited exophthalmos and strabismus occurs in Jersey cattle.

**Facial nerve (CN VII)**

The facial nerve supplies motor fibers for movement of the ears, eyelids, lips, and nostrils, in addition to the motor pathways of the menace, palpebral, and corneal reflexes. The symmetry and posture of the ears, eyelids, and lips are the best criteria for assessing the function of the nerve. Ability to move the muscles in question can be determined by creating a noise or stubbing a finger at the eye. Absence of the eye preservation reflex may be due to facial nerve paralysis or blindness. Facial paralysis is evidenced by ipsilateral drooping of the ear, ptosis of the upper eyelid, drooping of the lips and pulling of the filtrum to the unaffected side. There may also be drooling of saliva from the

</table>

In severe cases, rotation of the head is extreme, the animal is unable to stand and lies in lateral recumbency; moving to achieve this posture is compulsive and forceful. There is no loss of strength. In some species there is a relatively common occurrence of paralysis of the facial and the vestibular nerves as a result of otitis interna and otitis media. This does occur in the horse but less commonly than traumatic injury to the skull as a result of falling.

Pendular nystagmus should not be mistaken as a sign of serious neurological disease. Pendular nystagmus is characterized by oscillations of the eyeball that are always the same speed and amplitude and appear in response to a visual stimulus, e.g. a flashing light. Pendular nystagmus is observed most frequently in Holstein-Friesian cattle (prevalence of 0.51% in 2932 Holstein-Friesian and Jersey cows), and is not accompanied by other signs and there is no detectable histological lesion. A familial relationship was observed in Ayrshire bulls in Finland.
The glossopharyngeal nerve is sensory from the pharynx and larynx, and the vagus nerve is motor to these structures. Dysfunction of these nerves is usually accompanied by paralysis of these organs with signs of dysphagia or inability to swallow, regurgitation through the nostrils, abnormality of the voice and interference with respiration.

Because of the additional role of the vagus nerve in supplying nerve fibers to the upper alimentary tract, loss of vagal nerve function will lead to paralysis of the pharynx and esophagus. Parasympathetic nerve fibers to the stomach are also carried in the vagus and damage to them could cause hypomotility of that organ. The principal clinical finding in vagus nerve injury is laryngeal and pharyngeal paralysis.

Spinal accessory nerve (CN XI)
Damage to this nerve is extremely rare and the effects are not documented. Based on its anatomical distribution loss of function of this nerve could be expected to lead to paralysis of the trapezius, brachiocephalic and sternocleidomastoid muscles and lack of resistance to lifting the head.

Hypoglossal nerve (CN XII)
As the motor supply to the tongue, the function of this nerve can be best examined by observing the motor activity of the tongue. There may be protrusion, deviation or fibrillation of the organ, all resulting in difficulty in prehending food and drinking water. The most obvious abnormality is the ease with which the tongue can be pulled out. The animal also has difficulty in getting it back into its normal position in the mouth, although diffuse cerebral disease can also produce this clinical sign. In lesions of some duration there may be obvious unilateral atrophy.

**POSTURE AND GAIT**
The examiner evaluates posture and gait to give a general assessment of brainstem, spinal cord and peripheral nerve and muscle function. Evaluation of posture and gait consists of determining which limbs are abnormal and looking for evidence of lameness suggesting a musculoskeletal gait abnormality. Weakness and ataxia are the essential components of gait abnormality. Each limb is examined for evidence of these abnormalities. This is done while the animal is standing still, walking, trotting, turning tightly (pivoting) and backing up. To detect subtle asymmetry in the length of the stride, the observer should walk parallel to or behind the animal, step for step. If possible, the gait should also be evaluated while the animal is walking up and down a slope, walking with the head and neck held extended, while blindfolded and while running free in an enclosure.

The best observations are made when the animal is running free, preferably at a fast gait, to avoid abnormalities resulting from being led. Also, slight abnormalities such as a high-stepping gait, slight incoordination of movement, errors of placement of feet, stumbling and failure to flex joints properly are all better observed in a free animal. Weakness or paresis is evident when an animal drags its limbs, has worn hooves or has a low arc to the swing phase of the stride. When an animal bears weight on a weak limb, the limb often trembles and the animal may even collapse on that limb because of lack of support. While circling, walking on a slope and walking with the head held elevated, an animal frequently will stumble on a weak limb and knuckle over on the fetlock.

The presence of weakness in the limbs of horses or cattle can be determined by pulling the tail while the animal is walking forward. A weak animal is easily pulled to the side and put off stride. While the animal is circling, the examiner can pull on the lead rope and tail simultaneously to assess strength. Ease in pulling the animal to the side occurs because of weakness due to lesions of descending upper motor neuron pathway, the ventral
motor neuron lesions, the weakness is often so marked that it is easy to pull an animal to the side while it is standing or walking. In contrast, a weak animal with a lesion of the upper motor neuron pathways will often fix the limb in extension, reflexly, when pulled to one side. It resists the pull and appears strong.

**Severe weakness in all four limbs,** but with no ataxia and spasticity, suggests neuromuscular disease. Obvious weakness in only one limb is suggestive of a peripheral nerve or muscle lesion in that limb.

Ataxia is an unconscious, general proprioceptive deficit causing poor coordination when moving the limbs and

The sense of touch (tactile) is the ability to recognize objects and determine their properties by means of light touch. It is a primary sensory modality, and its loss can be caused by a variety of conditions, including peripheral neuropathies, spinal cord injuries, and central nervous system disorders. The sensation of touch is mediated by Aβ fibers, which are low-threshold mechanoreceptors that respond to gentle touch and light pressure. These fibers are present in the skin, muscle, and connective tissue and are responsible for the detection of light and moderate mechanical stimuli.

In humans, tactile sensation is divided into two main categories: discriminative touch and pressure sensation. Discriminative touch is the ability to distinguish between different stimuli, such as different textures or patterns. It is mediated by both Aβ and C fibers. Pressure sensation, on the other hand, is the ability to perceive light pressure and is mediated by C fibers only.

The sense of pain (nociception) is a complex phenomenon that involves both sensory and affective components. It is triggered by noxious stimuli, such as heat, cold, mechanical pressure, or chemical irritation. The pain pathway is a series of neural structures that transmit pain signals from the peripheral to the central nervous system. It involves both Aβ and C fibers, which are responsible for the transmission of pain signals from the periphery to the spinal cord and brain.

The sense of temperature is the ability to perceive changes in temperature. It is mediated by both Aβ and C fibers, which are sensitive to changes in skin temperature. The temperature sense is important for maintaining body temperature and for detecting changes in the environment, such as hot or cold objects.

Ataxia is an unconscious, general proprioceptive deficit causing poor coordination when moving the limbs and
the body. It results in swaying from side to side of the pelvis, trunk and sometimes the entire body. It may also appear as a weaving of the affected limb during the swing phase. This often results in abducted or abducted foot placement, crossing of the limbs or stepping on the opposite foot, especially when the animal is circling or turning tightly. Circumduction of the outside limbs when turning and circling is also considered a proprioceptive deficiency. Walking an animal on a slope, with the head held elevated, often exaggerates ataxia, particularly in the pelvic limbs. When a weak and ataxic animal is turned sharply in circles, it leaves the affected limb in one place while pivoting around it. An ataxic gait may be most pronounced when an animal is moving freely, at a trot or canter, especially when attempting to stop. This is when the limbs may be wildly abducted or adducted. Proprioceptive deficits are caused by lesions affecting the general proprioceptive sensory pathways, which relay information on limb and body position to the cerebellum (unconscious proprioception) and to the thalamus and cerebral cortex (conscious proprioception).

**Knuckling the flexed foot** while the animal stands on the dorsum to determine how long the animal leaves the foot in this state before returning it to a normal position is a test for conscious proprioception in dogs and cats. The test has not been useful in horses and adult cattle but is useful in sheep, goats, New World camels, and calves. Depressed animals will often allow the foot to rest on the dorsum for prolonged periods. Crossing the limbs and observing how long the animal maintains a crossed-legged stance has been used to test conscious proprioception.

**Hypermetria** is used to describe a lack of direction and increased range of movement, and is seen as an overreaching of the limbs with excessive joint movement. Hypermetria without paresis is characteristic of spino-cerebellar and cerebellar disease.

**Hypometria** is seen as stiff or spastic movement of the limbs with little flexion of the joints, particularly the carpal and tarsal joints. This generally is indicative of increased extensor tone and of a lesion affecting the descending motor or ascending spino-cerebellar pathways to that limb. A hypometric gait, particularly in the thoracic limbs, is best seen when the animal is backed up or when it is maneuvered on a slope with the head held elevated. The thoracic limbs may move almost without flexing.

**Dysmetria** is a term that incorporates both hypermetria and hypometria. Animals with severe cerebellar lesions may have a high-stepping gait but have limited movement of the distal limb joints, especially in thoracic limbs.

The degree of weakness, ataxia, hypometria and hypermetria should be graded for each limb. The types of gait abnormalities and the degree of weakness reflect various nervous and musculoskeletal lesions. Generally, with focal, particularly compressive, lesions in the cervical spinal cord or brainstem, neurological signs are one grade more severe in the pelvic limbs than in the thoracic limbs. Thus, with a mild, focal, cervical spinal cord lesion there may be more abnormality in the pelvic limbs with no signs in the thoracic limbs. The anatomical diagnosis in such cases may be a thoracolumbar, cervical, or diffuse spinal cord lesion.

A moderate or severe abnormality in the pelvic limbs, and none in the thoracic limbs, is consistent with a thoracolumbar spinal cord lesion. With a mild and a severe change in the thoracic and the pelvic limb gaits respectively, one must consider a severe thoracolumbar lesion plus a mild cervical lesion, or a diffuse spinal cord disease.

Lesions involving the brachial intumescence (spinal cord segments C6–T2) with involvement of the gray matter supplying the thoracic limbs, and diffuse spinal cord lesions may both result in severe gait abnormality in the thoracic limbs and the pelvic limbs.

A severely abnormal gait in the thoracic limbs, with normal pelvic limbs, indicates lower motor neuron involvement of the thoracic limbs; a lesion is most likely to be present in the ventral gray columns at spinal cord segments C6–T2 or thoracic limb peripheral nerves of muscle.

Gait abnormalities can occur in all four limbs, with lesions affecting the white matter in the caudal brainstem, when head signs, such as cranial nerve deficits, are used to define the site of the lesion. Lesions affecting the cerebrum cause no change in gait or posture.

**NECK AND FORELIMBS**

If a gait abnormality was evident in the thoracic limbs and there was no evidence of brain involvement, then examination of the neck and forelimbs can confirm involvement of the spinal cord, peripheral nerves (spinal cord segments C1–T2) or thoracic limb muscles. The neck and forelimbs are examined for evidence of gross skeletal defects, asymmetry of the neck and muscle atrophy. The neck should be manipulated from side to side and up and down to detect any evidence of resistance or pain. Localized unilateral sweating of the neck and cranial shoulder is evidence of Horner's syndrome, in which there are varying degrees of ptosis, prolapse of the third eyelid, miosis, enophthalmos and increased temperature of the face, neck and shoulder. The syndrome is associated with lesions affecting the descending sympathetic fibers in the white matter of the spinal cord or gray matter in the cranial thoracic segments, thoracocervical sympathetic trunk, cervical vagosympathetic trunk or cranial cervical ganglion and its pre- and post-ganglionic fibers.

**Sensory perception from the neck and forelimbs** is assessed using a painful stimulus such as a blunt needle or forceps. The local responses as well as the cerebral responses are noted when the skin over the shoulders and down the limbs is pricked.

**Gait deficits** are evaluated by making the horse or halter-broken ruminant perform a series of movements. Such exercises should include walking and trotting in a straight line, in large circles, in tight circles, backing on a level ground and on a slight slope, walking and trotting over curbs or low obstacles, walking in straight lines and circles, and walking on a slope with the head held elevated. The sway reaction for the thoracic limb is assessed by pushing against the shoulders and forcing the animal first to resist and then to take a step laterally. This can be done while the animal is standing still and walking forward. Pulling the tail and lead rope laterally at the same time will assess the strength on each side of the body. Making the animal turn in a tight circle by pulling the lead rope and tail at the same time will indicate strength; an adult horse should be able to pull the examiner around and should not pivot on a limb or be pulled to the side. Pressing down with the fingers on the withers of a normal animal causes some arching, followed by resistance to the downward pressure. An animal with weakness in the thoracic limbs may not be able to resist this pressure by fixing its vertebral column but will arch its back more than normal and often buckle in the thoracic limbs.

In smaller farm animal species, other postural reactions can be performed. These include wheelbarrowing and the hopping response test. The spinal reflexes are assumed to be intact in animals that are ambulating normally.

If a large mature horse, cow or pig has a gait abnormality, it is very rare to cast the animal to assess the spinal reflexes. However, spinal reflexes are usually examined in calves, sheep, and goats.

A **recumbent animal** that can use its thoracic limbs to sit up in the dog-sitting position may have a lesion caudal to spinal cord segment T2. If a recumbent...
animal cannot attain a dog-sitting position, the lesion may be in the cervical spinal cord. In lambs aged between 4 and 10 weeks with thoracic vertebral body abscesses extending into the epidural space causing spinal cord compression, the thoracic limbs are normal and the lambs frequently adopt a 'dog-sitting' position and move themselves around using the thoracic limbs only. Lambs with a cervical spinal cord lesion are unable to maintain sternal recumbency and have paresis of all four limbs.

However, mature cattle with the abomasal impactions secondary to hypocalcemia may be unable to use both the thoracic and pelvic limbs. If only the head, but not the neck, can be raised off the ground, there may be a severe cranial cervical lesion. With a severe caudal cervical lesion, the head and neck can usually be raised off the ground but thoracic limb function is decreased and the animal is unable to maintain sternal recumbency.

**Assessment** of limb function is done by manipulating each limb separately, in its free state, for muscle tone and sensory and motor activity. A limb that has been laid upon for some time cannot be properly evaluated because there will be poor tone from the compression. A flaccid limb, with no motor activity, indicates a lower motor lesion to that limb. A severe upper motor neuron lesion to the thoracic limbs causes decreased, or absent, voluntary effort, but there is commonly normal or increased muscle tone in the limbs. This is due to release of the lower motor neuron, which reflexly maintains normal muscle tone from the calming influence of the descending upper motor neuron pathways.

**The tone of skeletal muscle** may be examined by passively flexing and extending the limbs and moving the neck from side to side and up and down. Increased muscle tone, spasticity or tetany may be so great that the limb cannot be flexed without considerable effort. If the spastic-extended limb does begin to flex but the resistance remains, this is known as 'lead-pipe' rigidity, which is seen in tetanus. If after beginning to flex an extended spastic limb, the resistance suddenly disappears ('clasp-knife release') this suggests an upper motor neuron lesion, as occurs in spastic paresis in cattle.

**Flaccidity, or decreased muscle tone**, indicates the presence of a lower motor neuron lesion with interruption of the spinal reflex arc.

Localized atrophy of muscles may be myogenic or neurogenic and the difference can be determined only by electromyography, a technique not well suited to large-animal practice. If the atrophic muscle corresponds to the distribution of a peripheral nerve it is usually assumed that the atrophy is neurogenic. In addition, neurogenic atrophy is usually rapid (will be clinically obvious in a few days) and much more marked than either disuse or myogenic atrophy.

**Spinal reflexes of the thoracic limbs**

These include the flexor reflex, the biceps reflex and the triceps reflex. The flexor reflex is tested by stimulation of the skin of the distal limb and observing for flexion of the fetlock, knee, elbow, and shoulder. The reflex arc involves sensory fibers in the median and ulnar nerves, spinal cord segments C5–T2 and motor fibers in the axillary, musculocutaneous, median and ulnar nerves. Lesions cranial to spinal cord segment C6 may release this reflex from the calming effect of the upper motor neuron pathways and cause an exaggerated reflex with rapid flexion of the limb, and the limb may remain flexed for some time. A spinal reflex may be intact without cerebral perception. Cerebral responses to the flexor reflex include changes in the facial expression, head movement toward the examiner and vocalization. Conscious perception of the stimulus will be intact only as long as the afferent fibers in the median and ulnar nerves, the dorsal gray columns at spinal cord segments C6–T2 and the ascending sensory pathways in the cervical spinal cord and brainstem are intact.

**The laryngeal adductory reflex** is of special interest in the examination of ataxic horses. In normal horses a slap on the saddle region just caudal to the withers causes a flickering adductory movement of the contralateral arytenoid cartilage that is visible by an endoscope. Reflex muscle contraction can be palpated on the dorsolateral surfaces of the larynx. The reflex is absent when there is damage to afferent tracts up the spinal cord, when there is damage to the recurrent laryngeal nerves, and in tense or frightened horses. Elicitation of the reflex is called the slap test.

**TRUNK AND HINDLIMBS**

If examination of the posture, gait, head, neck or thoracic limbs reveals evidence of a lesion, then an attempt should be made to explain any further signs found during examination of the trunk and hindlimbs that could have been caused by the lesion. If there are only signs in the trunk and hindlimbs, then the lesion(s) must be either between spinal cord segments T2 and S2 or in the trunk and pelvic limb nerves or muscles. It must be remembered that a subtle neurological gait in the pelvic limbs may be anywhere between the mid sacral spinal cord and the rostral brainstem.

The trunk and hindlimbs are observed and palpated for malformations and asymmetry. Diffuse or localized sweating, the result of epinephrine release and sympathetic denervation, is often present in horses affected with a severe spinal cord injury.

**Gentle pricking** of the skin over the trunk and over the lateral aspects of the body, including on either side of the thoracolumbar vertebral column, will test-stimulate the cutaneous trunci reflex. The sensory stimulus travels to the spinal cord in thoracolumbar spinal nerves and the animal will attempt to scratch at the point of stimulation. These impulses are transmitted up the spinal cord to spinal cord segments C8–T1, where the lateral thoracic nerve is stimulated, causing contraction of the cutaneous trunci muscle, which is seen as a flicking of the skin over the trunk. Lesions anywhere along this pathway will result in suppression or absence of this reflex caudal to the site of the lesion. Degrees of hypalgesia and analgesia have been detected caudal to the sites of thoracolumbar spinal cord lesions, especially if they are severe. In mature cattle with fractured thoracolumbar vertebral column associated with traumatic injury or vertebral body abscesses in calves, the site of the lesion may be able to be localized with this reflex. Sensory perception of pinpricking the trunk and hindlimbs may also be absent caudal to the lesion.

**The sway reaction** for the pelvic limbs involves pushing against the pelvis and pulling on the tail with the animal standing still and walking forward. An animal which is weak in the pelvic limbs will be easily pulled and pushed laterally, especially while walking. Proprioceptive deficits can be observed as overabduction and crossing of the limbs when a step is taken to the side.

**Pinching** and pressing down on the thoracolumbar or sacral paravertebral muscles with the fingers causes a normal animal to extend slightly, then fix, the thoracolumbar vertebral column. It also resists the ventral motion and usually does not flex the thoracic or pelvic limbs. A weak animal usually is not able to resist the pressure by fixing the vertebral column and thus it overextends the back and begins to buckle in the pelvic limbs.

In the **recumbent animal**, examination of the pelvic limbs includes the pelvic limb spinal reflexes, the degree of voluntary effort and the muscle tone present. Observing the animal attempting to rise on its own or following some cueing will help to assess the pelvic limbs. The flexor spinal reflex is performed by pinching the skin and observing the flexion of the limb; central perception of the painful stimulus is also noted. The afferent and efferent pathways for this
The patellar reflex is evaluated by placing the animal in lateral recumbency and supporting the limb in a partly flexed position. The intermediate patellar ligament (horses) or patellar ligament (ruminants, pigs, New World camelds) is then tapped with a heavy metal plexor. This results in extension of the stifle joint. The sensory and motor fibers for this reflex are in the femoral nerve, and the spinal cord segments are L4 and L5. The patellar reflex is hyperactive in newborn farm animals. The gastrocnemius reflex and the cranial tibial reflex are not evaluated because they cannot be reliably induced.

The spinal cord of the calf has more control of basic physical functions than in humans, dogs and horses. For example, calves are able to retain control of the pelvic limb in spite of experimentally induced lesions that cause hemiplegia in dogs and humans. Also transection of the spinothalamic tract in the calf cord does not produce an area of hypalgesia or analgesia on the contralateral side as such a lesion would do in a human.

Tail tone is evaluated by lifting the tail and noting the resistance to movement. A flaccid tail, with no voluntary movement, is indicative of a lesion of the sacrococcygeal spinal cord segments, nerves, or muscles. Decreased tone in tail can be detected with severe spinal cord lesions cranial to the coccygeal segment.

Skin sensation of the pelvic limbs should be assessed independently from reflex activity. The femoral nerve is sensory to the skin of the medial thigh region, the peroneal nerve to the dorsal tarsus and metatarsus, and the iliac nerve to the plantar surface of the metatarsus.

**Tail and Anus**

Tail tone is evaluated by lifting the tail and noting the resistance to movement. A flaccid tail, with no voluntary movement, is indicative of a lesion of the sacrococcygeal spinal cord segments, nerves, or muscles. Decreased tone in tail can be detected with severe spinal cord lesions cranial to the coccygeal segment.

The perineal reflex is elicited by lightly pricking the skin of the perineum and observing reflex contraction of the anal sphincter and clamping down of the tail. The sensory fibers are contained within the perineal branches of the pudendal nerve (spinal cord segments S1–S3). Contraction of the anal sphincter is mediated by the caudal rectal branch of the pudendal nerve, and tail flexion is mediated by the sacral and coccygeal segments and nerves (spinal cord segments S1–Co). An animal with a flaccid tail and anus, due to lower motor neuron lesion, will not have an anal or tail reflex. However, it may still have normal sensation from the anus and tail provided that the sensory nerves and spinal cord and brainstem white matter nociceptive pathways are intact.

Observation of defecation and urination movements and postures contributes to knowledge of the state of the cauda equina. Thus nealresis of the cauda equina is characterized by flaccid paralysis and analgesia of the tail, anus and perineum, rectum and bladder. There is no patellar or analysis of the hindlimbs unless lumbosacral segments of the cord are damaged.

**PALPATION OF THE BONY ENCASEMENT OF THE CENTRAL NERVOUS SYSTEM**

Palpable or visible abnormalities of the cranial or spinal column are not commonly encountered in diseases of the nervous system but this examination should not be neglected. There may be displacement, abnormal configuration or pain on deep palpation. These abnormalities are more readily palpable in the vertebral column and if vertebrae are fractured. Abnormal rigidity or flexibility of the vertebral column, such as occurs in atlanto-occipital malformations in Arabian horses and cattle, may also be detectable by manipulation.

**COLLECTION AND EXAMINATION OF CEREBROSPINAL FLUID**

The collection and laboratory analysis of CSF from farm animals with clinical evidence of nervous system disease can provide useful diagnostic and prognostic information.

CSF is formed mostly from the choroid plexuses of the lateral ventricles by the ultrafiltration of plasma and the active transport of selected substances across the blood-brain barrier. The CSF in the ventricular system flows caudally and diffuses out of the lateral aperture in the fourth ventricle to circulate around the brain and spinal cord. The presence of CSF in the subarachnoid space separates the brain and spinal cord from the bony cranial and vertebral column, which reduces trauma to the underlying delicate nervous tissue. CSF also has excretory functions with the removal of products of cerebral metabolism.

Collection of cerebrospinal fluid

CSF can be collected from lumbosacral cistern with sedation (horses) or restraint (ruminants) and the atlanto-occipital cistern (cisterna magna) using injectable general anesthesia. For collection it is necessary to puncture the subarachnoid space in both the lumbosacral space or cisterna magna. Although there is no substantial difference between the composition of lumbosacral or cisternal CSF samples unless there is a compressive lesion of the spinal cord, the general policy is to sample as close to the lesion as possible. CSF should be collected into a sterile tube and there is no need to add an anticoagulant, even in samples visibly contaminated with blood. Cytology should be performed as soon as possible after collection (ideally within 15 min) because the cells rapidly degenerate.

Collection from the lumbosacral cistern

The lumbosacral site is preferred because general anesthesia is not required. CSF can be collected from the lumbosacral cistern with relative ease provided that adequate restraint can be achieved and the anatomical landmarks can be identified. CSF can be collected from the standing or recumbent animal. If recumbent, the animal should be placed in sternal recumbency with hips flexed and the pelvic limbs extended alongside the abdomen. This widens the lumbosacral space to permit correct placement of the spinal needle.

The site for collection is the midpoint of the lumbosacral space, which can be identified as the midline depression between the last palpable dorsal lumbar spine (L6 in cattle, goats and horses; L6 or L7 in sheep and pigs; L7 in New World camels) and the first palpable sacral dorsal spine (usually S2). In well-conditioned animals, these landmarks cannot always be identified; in which case the site is identified as the midpoint of a line connecting the caudal aspect of the tuber coxae. The site is clipped, surgically prepared and 1–2 mL of local anesthetic is administered subcutaneously. Sterile surgical gloves should be worn. Hypodermic spinal needles with stilettes are recommended because ordinary needles commonly plug with tissue. The length and gauge of needle depends on the size of the animal, but 15 cm (6 in) 18-gauge needles are needed for adult horses and cattle. The following guide is recommended (Table 12.7).

Provided the animal is well restrained and care is exercised in introducing the needle, little difficulty should be encountered. For collection from the lumbosacral space the needle is slowly advanced

perpendicular or up to 15° caudal to perpendicular to the plane of the vertebral column. The needle must be introduced in a perfectly vertical position relative to the plane of the animal's vertebral column because of the danger of entering one of the lateral blood vessels in the vertebral canal. Changes in tissue resistance can be felt as the needle point passes sequentially through the subcutaneous tissue, interarcuate ligament, then the sudden 'pop' due to the loss of resistance as the needle point penetrates the ligamentum flavum into the epidural space. Once the needle point has penetrated the dorsal subarachnoid space, CSF will well up in the needle hub within 2-3 seconds. Failure to appreciate the changes in resistance as the needle moves down may result in puncture of the conus medullaris, which may elicit an immediate neurological disease confined to the hind limbs, CSF may be difficult to obtain because of fibrosis of the epidural tissue.23 Careful aspiration with a syringe attached to the needle held between the thumb and index finger is usually required to obtain a sample of 2-3 mL, which is sufficient for laboratory analysis. This can be facilitated by firmly resting the forearms and wrists on the animal's back. Failure to obtain fluid is usually due to incorrect direction of the needle, in which case the bony landmarks of the lumbosacral space (depression) must be rechecked and, with the needle correctly realigned, the procedure repeated. In animals with a vertebral body abscess and neurological disease confined to the hind limbs, CSF may be difficult to obtain from the lumbosacral space because flow is occluded. In these circumstances, if a sample is obtained, the CSF protein may be increased as a result of stagnation of CSF distal to the lesion with exudation or transudation of protein from the lesion (Froin's syndrome).24

Collection from the atlanto-occipital cistern (cisterna magna) This site is preferred for intracranial lesions because the fluid is produced in the subarachnoid space and flows caudally down the spinal cord.25 However, this site is rarely used because of the inherent risk of needle penetration of the brainstem. Xylazine at 0.20 mg/kg body weight (BW) intramuscularly is effective in providing adequate sedation and analgesia for this procedure in cattle. A general anesthetic (such as combined intravenous administration of xylazine and ketamine) is recommended for horses.

The site is prepared as with the lumbosacral cistern. Ventreflexion of the head and neck of cattle enlarges the space of the cisterna magna and allows easy entry using a stilleted spinal needle inserted at a point created by the transection of the transverse line of the cranial rim of the wing of the atlas and the dorsal midline. The needle is advanced carefully and steadily and the tip is directed rostrally towards the symphysis of the lower jaw. The needle point goes through the skin, ligamentum nuchae and leptomeninges. In most mature cattle of body weight over 500 kg, a 20-gauge, 10 cm (4 in) spinal needle will enter the cisterna magna at 5-7 cm after going through the ligamentum nuchae, which provides some increased resistance. When the needle point punctures the leptomeninges, the animal may move its head slightly. At that point the needle is advanced only 1-2 mm and the stillette is then removed. If the end of the needle is in the cisterna magna, CSF will flow out of the needle freely and the manometer can be attached and the pressure measured.

Cerebrospinal fluid pressure

The CSF pressure can be determined by the use of a manometer attached to the spinal needle. Normal CSF pressures of the cisterna magna in cattle and xylazine/ketamine-anesthetized horses range from 5-15 cm (uncertain reference point) and 28 ± 4 cm (referenced to the right atrium), respectively, using 0.9% NaCl solution in a manometer.26 When the fluid system is properly connected, occlusion of both jugular veins causes a marked rise in CSF pressure; this is called Querckenstedt's test. The Querckensted test involves bilateral jugular vein compression; this results in a sudden increase in intracranial subarachnoid pressure that is transmitted to the cranial subarachnoid space. The resultant CSF pressure wave is transmitted to the lumbar area (when obtaining CSF from the lumbosacral space) in the absence of an obstruction in the spinal subarachnoid space, thereby resulting in an increased flow of CSF.

Variations in CSF pressure are not of much use in clinical diagnosis except in hypovitaminosis A, and measurement of CSF pressure is only indicated in animals with signs of cerebral disease (abnormal mentation). Care is needed in interpreting results because the pressure is greatly affected by voluntary movement such as tenesmus. CSF pressure is increased in a number of diseases, including poliomyelomalacia, bacterial meningitis, and hypovitaminosis A. Xylazine given intravenously causes a decrease in intracranial pressure in healthy conscious horses.27 Epidural pressure of cattle changes with change in position from standing to lateral recumbency to dorsal recumbency, and epidural pressure is positive in laterally recumbent animals.28 Although the effect of epidural pressure on CSF pressure has not been evaluated in large animals, it is likely that CSF pressure is also affected by position.

Analysis of cerebrospinal fluid

Analysis of CSF has greater diagnostic value than hematology in animals with nervous system disease. CSF can be examined for the presence of protein, cells and bacteria.2 The white blood cell count in normal animals is usually less than 5 cells/μL but a report exists of higher counts (12-200 cells/μL) in sheep.2 An increase in CSF leukocyte count above 5 cells/μL is termed a pleocytosis and is categorized as mild (6-49 cells/μL), moderate (50-200 cells/μL) or marked (>200 cells/μL). The differential white cell count comprises mostly lymphocytes and monocytes; there are no erythrocytes in normal animals. Samples that show visible turbidity usually contain large numbers of cells (>500 cells/μL) and much protein. In cattle, protein concentrations range from 23-6 mg/dL, sodium concentrations from 132-144 mmol/L, potassium 2.7-3.2 mmol/L, magnesium 1.8-2.1 mEq/L and glucose concentrations 37-51 mg/dL.29 In the horse, the reference values for CSF are similar.30 Neonatal foals under 3 weeks of age have higher CSF protein concentrations than do adult horses. Glucose concentrations peak in the first 48 hours after birth, then decrease to adult values by the second week of life. Concentrations of sodium and potassium are not affected by age and are similar to values reported for adult horses and ponies.

With bacterial infections of the nervous system the CSF concentration of protein will be increased and the white blood cell count increased up to 2000 cells/μL with more than 70% neutrophils.31 A neutrophilic pleocytosis is considered 95-100% indicative of an inflammatory process within the central nervous system.32 Theoretically, the CSF glucose concentration will be decreased and CSF lactate concentration will be increased in animals with bacterial meningitis because of bacterial metabolism, but these are unreliable signs and usually do not provide additional information to that provided by determination of CSF leukocyte and protein concentrations.

Bacteria may also be cultured from the CSF. Because meningencephalitis may occur concurrently or following acute
diarrhea in calves under a few weeks of age, the evaluation of CSF should be considered in calves that remain depressed and inactive following rehydration and treatment.31

The creatine kinase and lactate dehydrogenase activities in CSF have been examined as an aid in the differentiation of some neurological diseases. However, creatine kinase activity is considered to be unreliable; contamination of the sample with epidural fat and dura may increase CSF creatine kinase activity in the horse.32 Insufficient information is available to evaluate the clinical utility of CSF lactate dehydrogenase activity in large animals.

The CSF glucose concentration is usually 60-80% of serum glucose concentration; this steady state value reflects facilitated transport across the blood–brain barrier, absence of binding proteins for glucose in CSF and nervous tissue metabolism of glucose.29 However, sudden changes in plasma glucose concentrations are not immediately reflected in CSF glucose concentrations, because CSF turns over at around 1% per minute. Typically, a lag time of up to 3 hours is needed for CSF glucose concentration to be in equilibrium with plasma glucose concentrations. Hyperglycemia as a result of the stress of handling and restraint may therefore not be reflected by an increased CSF glucose concentration.

Blood contamination of CSF can make interpretation difficult. A formula has been developed that ‘corrects’ the CSF values for the degree of blood contamination, based on the red blood cell count in CSF (RBCCSF) and blood (RBCblood), whereby the corrected value for substance X in CSF (Xcorrected) and blood (Xblood) concentration is derived from the measured value of X in CSF (XCSF) and blood (Xblood) and applying the following formula:

\[ X_{\text{corrected}} = X_{\text{CSF}} - (X_{\text{blood}} \times \frac{\text{RBC}_{\text{CSF}}}{\text{RBC}_{\text{blood}}}) \]

Calculation of a ‘corrected’ value rarely provides additional insight into the CSF analysis and is not commonly practiced in large animals.

Protein fractionation of CSF is not routinely performed because it requires sensitive electrophoresis methodology or species-specific radial immunodiffusion assays. However, calculation of the albumin quotient and IgG index may be informative in specific neurologic diseases.34,35 Theoretically, these calculations can differentiate four blood–brain permeability patterns: normal blood–brain barrier permeability (normal albumin quotient and IgG index); intrathecal IgG production with normal blood–brain barrier permeability (normal albumin quotient and increased IgG index); increased blood–brain barrier permeability without intrathecal IgG production (increased albumin quotient and normal IgG index) and increased blood–brain barrier permeability with intrathecal production of IgG (increased albumin quotient and increased IgG index). The albumin quotient is calculated from the albumin concentration in CSF (ALBCSF) and serum (ALBS serum), whereby:

\[ \text{Albumin Quotient} = \frac{(\text{ALB}_{\text{CSF}})}{(\text{ALB}_{\text{serum}})} \times 100 \]

The normal value for albumin quotient in the adult horse is less than 2.23,36 but the mean is 0.4 to 0.5 in cattle and adult llamas.29,37 Because CSF protein is most commonly derived by disturbance of the blood–brain barrier and inflammation (resulting in an increased CSF albumin concentration), an increased CSF protein concentration is usually accompanied by an increased albumin quotient.

In animals suspected to have increased immunoglobulin production in the central nervous system (a rare occurrence, and almost always accompanied by disturbance of the blood–brain barrier), the IgG index can be calculated from the IgG concentration in CSF (IgGCSF) and serum (IgGserum), and the albumin concentration in CSF (ALBCSF) and serum (ALBS serum), whereby:

\[ \text{IgG Index} = \frac{(\text{IgG}_{\text{CSF}}/\text{IgG}_{\text{serum}})}{(\text{ALB}_{\text{serum}}/\text{ALB}_{\text{CSF}})} \times \]

An IgG index of more than 0.3 is suspected to indicate intrathecal IgG production in the adult horse.34 This formula corrects the CSF IgG concentration for an increased permeability of the blood–brain barrier, and therefore theoretically provides a more sensitive method for detecting local production of IgG within the central nervous system. Calculating the albumin quotient and IgG index is expensive and rarely provides additional information to that provided by CSF protein concentration alone, and for this reason is not commonly performed in large animals.

In summary, collection and analysis of CSF from the lumbosacral region provides a practical, safe and informative diagnostic tool in conscious large animals with neurological disease. Analysis of CSF in animals with central nervous system disease has greater diagnostic value than analysis of the leukor or serum biochemical analysis. Routine assessment of CSF should include total protein concentration, erythrocyte count, leukocyte count and leukocyte differential count. Other analytical procedures on CSF can be performed in specific diseases related to the nervous system.

EXAMINATION OF THE NERVOUS SYSTEM WITH SERUM BIOCHEMICAL ANALYSIS

Arterial plasma ammonia concentration

In animals suspected of having hepatic encephalopathy, measurement of the arterial plasma ammonia concentration provides a clinically useful diagnostic test and a means of monitoring the response to treatment. In monogastrics, ammonia is produced by bacterial degradation of amines, amino acids, and purines in the gastrointestinal tract, by the action of bacterial and intestinal urease on urea in the gastrointestinal tract and by the catabolism of glutamine by enterocytes.37 In ruminants, ammonia is derived predominantly from bacterial metabolism in the rumen and catabolism of amino acids in tissue. Absorbed ammonia is normally converted to urea by the liver and to glutamine by the liver, skeletal muscle, and brain. In the presence of hepatic dysfunction, ammonia is inadequately metabolized, resulting in high plasma ammonia concentrations. Ammonia is a direct neurotransmitter that alters inhibitory and excitatory neurotransmission in the brain.

Hyperammonemia can be used as a specific indicator of hepatic dysfunction. Normal values for arterial plasma ammonia concentration are less than 29 μmol/L in adult cattle22 but may reach higher values in the immediate periparturient period. Arterial values are higher than venous values, and are preferred for analysis.

Blood gas analysis and serum electrolyte determination should be routinely undertaken in animals with clinical signs of encephalopathy, in order to rule out metabolic causes of cerebral dysfunction.

EXAMINATION OF THE NERVOUS SYSTEM WITH IMAGING TECHNIQUES

Radiography

Examination of the bony skeleton of the head and vertebral column to detect abnormalities which are affecting the nervous system of large animals is being used more commonly in referral centers. Conventional diagnostic radiography remains the best method for the initial evaluation of trauma to the brain and spinal cord. The injection of contrast media into the CSF system (myelography) is used for the detection of spinal cord compression but is rarely indicated in large animals because spinal cord depression surgery is rarely performed. In cases of peripheral nerve injury the radiograph of the appropriate limb may reveal the presence of a fracture or space-occupying lesion that has caused dysfunction of the peripheral nerve.
Computed tomography

Computed tomography (CT) of the skull has several advantages over radiography because structures are viewed in cross section without superimposition. The development of computer software and technology allows a large amount of information to be obtained from a CT examination. Numerous diseases of the head of the horse, including those of the brain, can be diagnosed using this technique, but the limiting factors are the weight of the patient, accessibility for large animals and the need for general anesthesia. General CT provides an excellent image of skeletal defects. CT has been used for the antemortem diagnosis of many conditions in foals and horses, and otitis interna in calves.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) scanning uses nuclear magnetic resonance to create cross sectional images based on the magnetic properties of tissues. In general, MRI provides an excellent image of soft tissue defects, but the limiting factors are the weight of the patient, accessibility for large animals and the need for general anesthesia. MRI has been used for the antemortem diagnosis of many neurological conditions in foals and horses and cerebellar hypoplasia in a calf.

RHINOLARYNGOSCOPY

Endoscopy (rhinolaryngoscopy) is now a routine technique for the examination of horses with suspected laryngeal hemiplegia. Oropharyngoscopy for the examination of the structures of the eye is important in the diagnosis of diseases affecting the optic nerve such as vitamin A deficiency, and the optic disc edema (papilledema) associated with diffuse cerebral edema.

ELECTROENCEPHALOGRAPHY

Electroencephalography (EEG) has not been utilized to any significant degree in large animals. The EEG requires sophisticated equipment, a quiet dim environment free from electrical interference and a quiet patient that has minimal muscular activity. Because of the difficulty in obtaining quality recordings in a conscious large animal, it is preferred that the animal is anesthetized for the recording, which may confound interpretation of the EEG pattern depending on the anesthetic protocol. Electroencephalography has therefore been primarily used as an antemortem or research tool in large animals, and its use will probably remain as a complementary test to other neurological examinations and diagnostic tests at referral institutions.

Recommendations have been made in order to standardize EEG techniques for animals, these typically involve meticulous preparation of the recording sites on the scalp, and placement of electrodes over the left and right frontal areas, the left and right occipital areas, the vertex area and a reference electrode is placed behind the tip of the nose. However, the addition of other recording sites increases the ability to localize a focal lesion. Neurological disease is associated with changes in either EEG frequency or amplitude, or both, with frequency changes being a more reliable indicator of disease. In general, focal EEG abnormalities indicate a focal lesion in the cortex, whereas diffuse EEG abnormalities indicate diffuse cortical or subcortical lesions or focal subcortical lesions.

Electroencephalography has been used to study epilepsy in goats and cattle, congenital hydranencephaly and hydrocephalus in cattle, scapie in sheep, thiamine-responsive polioencephalomalacia in cattle and bovine spongiform encephalopathy in cattle. When performed under controlled conditions, EEG has been shown to be a useful diagnostic tool for the early diagnosis of equine intracranial diseases, with adequate sensitivity and specificity.

BRAINSTEM AUDITORY EVOKED POTENTIALS

The brainstem auditory evoked potential (BAEP) is a recording of the electrical activity of the brainstem following an acoustic stimulus. The use of the BAEP is well documented in human medicine as a diagnostic aid and has been used in dogs to evaluate deafness. The BAEP is obtained by recording neuro-electrical activity from generators in the auditory pathway immediately following an acoustic click stimulus, and BAEP waveforms for horses and ponies have been recorded. Such recordings can be useful in evaluating horses suspected to have deafness, vestibular disease or brainstem disease, and to monitor the response to treatment.

INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION PRESSURE

Intracranial pressure has been measured in neonatal foals, although the clinical utility of such measurements has not been demonstrated. Increases in intracranial pressure can cause decreases in cerebral perfusion pressure and irreversible injury to the central nervous system.

Principles of treatment of diseases of the nervous system

Treatment of disease of the nervous system presents some particular problems because of the failure of nervous tissue to regenerate and because of the impermeability of the blood–brain barrier to many antimicrobial agents, antiprotozoal agents, and anthelmintics.

When peripheral nerves are severed, regeneration occurs if the damage is not extensive but no specific treatment, other than surgical intervention, can be provided to facilitate repair. When neurons are destroyed in the brain and spinal cord no regeneration occurs and the provision of nervous system stimulants can have no effect on the loss of function that occurs. The emphasis in the treatment of diseases
of the nervous system must be on prevention of further damage. On occasion this can be done by providing specific or ancillary treatments.

**ELIMINATION AND CONTROL OF INFECTION**

Most of the viral infections of the nervous system are not susceptible to chemotherapy. Some of the larger organisms such as *Chlamydia* spp. are susceptible to broad-spectrum antimicrobial agents such as the tetracyclines and chloramphenicol.

Bacterial infections of the central nervous system are usually manifestations of a general systemic infection as either bacteremia or septicemia. Treatment of such infections is limited by the existence of the blood–brain and blood–CSF barriers, which prevent penetration of some substances into nervous tissue and into the CSF. Very little useful data exist on the penetration of parenterally administered antibiotics into the central nervous system of either normal farm animals or those in which there is inflammation of the nervous system.

In humans it is considered that most antimicrobials do not enter the subarachnoid space in therapeutic concentrations unless inflammation is present, and the degree of penetration varies among drugs. Chloramphenicol is an exception; levels of one-third to one-half of the blood level are commonly achieved in normal individuals. The relative diffusion of Gram-negative antimicrobial agents from blood into CSF in humans is shown in Table 12.8.

The most promising antimicrobial agents for the treatment of bacterial meningitis in farm animals are the third-generation cephalosporins, trimethoprim–sulfonamide combinations and gentamicin.59 In most instances of bacterial encephalitis or meningitis in farm animals it is likely that the blood–brain barrier is not intact and that parenterally administered drugs will diffuse into the nervous tissue and CSF. Certainly, the dramatic beneficial response achieved by the early parenteral treatment of *Histophilus somni* meningoencephalitis in cattle using intravenous oxytetracycline, intramuscular penicillin or a broad-spectrum antibiotic suggests that the blood–brain barrier may not be a major limiting factor when inflammation is present. Another example of an antibiotic that does not normally pass the blood–brain barrier well but is able to do so when the barrier is damaged is penicillin in the treatment of listeriosis. When cases of bacterial meningoencephalitis fail to respond to antimicrobial agents, to which the organisms are susceptible, other reasons should also be considered. Often the lesion is irreversibly advanced or there is a chronic suppressive process which is unlikely to respond.

Intrathecal injections of antimicrobial agents have been suggested as viable alternatives when parenteral therapy appears to be unsuccessful. However, there is no evidence that such treatment is superior to appropriate parenteral therapy. In addition, intrathecal injections can cause rapid death and therefore are not recommended.

**DECOMPRESSION**

Increased intracranial pressure probably occurs in most cases of inflammation of the brain but it is only likely to be severe enough to cause physical damage in acute cerebral edema, space-occupying lesions such as abscesses, and hypovitaminosis A. In these circumstances some treatment should be given to withdraw fluid from the brain tissue and decrease the intracranial pressure.

One treatment that may be attempted is the combination of mannitol and corticosteroids used in man and in small animals. Mannitol given as a 20% solution intravenously over a 30-60-minute period is a successful intracranial decompressant with an effect lasting about 4 hours; the effect can be prolonged by the intravenous administration of dexamethasone 3 hours after the mannitol. The treatment has been used in calves with polioencephalomalacia, combined with thiamin, with excellent results to relieve the effects of acute cerebral edema. The dose rates have been those recommended for dogs and are very expensive: mannitol 2 g/kg BW, dexamethasone 1 mg/kg BW, both intravenously. There are dangers with mannitol: it should not be repeated often; it must not be given to an animal in shock; it should be given intravenously slowly. Dexamethasone on its own is safe and has a good effect but does not decompress sufficiently. Hypertonic glucose given intravenously is dangerous because an initial temporary decompression is followed after a 4–6-hour interval by a return to pretreatment CSF pressure when the glucose is metabolized.

**TREATMENT OF BRAIN INJURY AFTER HEAD TRAUMA**

The principles of treatment of animals exhibiting neurological abnormalities after a traumatic event are derived from the results of large, controlled, multicenter clinical trials in human beings. Similar studies have not been performed in large animals. The general principles are: 1) stabilize the patient by ensuring a patent airway, obtaining vascular access and attending to wounds, 2) specific treatment for hyperthermia as brain defects may result in an inability to regulate core temperature, 3) prevent or treat systemic arterial hypotension, 4) optimize oxygen delivery, 5) ensure adequate ventilation by placing in sternal recumbency whenever possible, 6) decrease pain, 7) monitor plasma glucose concentration and maintain euglycemia, and 8) prevent or treat cerebral edema by having the head elevated or by the intravenous administration of a hyperosmolar agent (hypertonic saline, 7.2% NaCl, 2 mL/kg BW every 4 hours for 5 infusions; 20% mannitol as a series of bolus infusions of 0.25 to 1 g/kg BW every 4–6 hours, the latter is an expensive treatment). Intravenous catheterization should be confined to one jugular vein and the neck should not be bandaged in an attempt to minimize promotion of cerebral edema by jugular venous hypertension. Seizures should be treated when they occur by administering diazepam, midazolam, phenobarbital, or pentobarbital.

Many anecdotal treatments have been used in large animals, but evidence attesting to their efficacy is clearly lacking. Amongst the more popular empiric anti-oxidant treatments are dimethyl sulfoxide (1 g/kg BW as a 10% solution in 0.9% NaCl) administered intravenously or by nasogastric tube every 12 h, vitamin E (α-tocopherol, 50 IU/kg BW administered orally every day), vitamin C (ascorbic acid, 20 mg/kg BW administered orally every day), and allopurinol (5 mg/kg BW administered orally every 12 h). Corticosteroids have also been advocated; promoted treatments include an anti-inflammatory dose of dexamethasone (0.05 mg/kg BW every day) or a high dose of methylprednisolone sodium succinate (30 mg/kg BW initial bolus, followed by continuous infusion of 5.4 mg/kg BW per hour for...
24-48 h); the latter treatment is prohibitively expensive in large animals and must be given within 8 hours of the traumatic event to be effective. Intravenous magnesium sulfate (50 mg/kg BW) in the first 5-10 L of intravenous fluids has also been advocated on the basis that it inhibits the cascade.

CENTRAL NERVOUS SYSTEM STIMULANTS

These substances are used to excess in many instances. They exert only a transitory improvement in nervous function and are indicated only in nervous shock and after anesthesia or other short-term reversible anoxias such as cyanide or nitrate poisoning. It is unlikely that terminal respiratory failure caused by anoxia over a long period, and in which anoxia is likely to continue, will respond permanently to their use.

CENTRAL NERVOUS SYSTEM DEPRESSANTS

Animals with convulsions should be sedated to avoid exciting traumatic injuries on themselves. Most of the general anesthetic agents in common use will satisfactorily control convulsions, and allow some time to examine the animal properly, assess the diagnosis and institute specific therapy if possible.

Pathophysiological mechanisms of nervous system disease

Etiology of nervous system disease

There are many different causes of nervous system disease in large domestic animals.

- Infectious causes include bacteria, viruses, fungi, and helmiths, arthropod and protozoan parasites
- Exogenous substances such as lead, salt, selenium, organophosphate insecticides, feed additives such as urea, poisonous plants and many other chemicals are common causes
- Endogenous substances such as products of disease in other body systems or of abnormal metabolism such as bacterial toxins, ammonia and carbon dioxide can cause abnormalities of the nervous system
- Metabolic and nutritional causes include ischemia secondary to cardiopulmonary disease, hypoglycemia, hypomagnesemia, copper deficiency in pregnant animals, and hyper D-lactatemia in calves with neonatal diarrhea and adult ruminants with grain overload
- Acidemia associated with diarrhea can cause mental depression and ataxia
- Traumatic and physical injuries to the brain or spinal cord are common
- Neoplasms of the nervous system in large animals are uncommon, with the exception of spinal lymphosarcoma in adult cattle due to enzootic bovine leukosis
- Idiopathic diseases account for several diseases of the spinal cord of horses
- Malformation occurs primarily in the developing fetus and results in congenital nervous system disease, which is usually present at birth. Many different teratogens can cause congenital defects. In some cases of inherited disease, the clinical signs are not manifest until some time after birth.

Responses of central nervous system to injury

The central nervous system may respond to injury by morphological changes that include cerebral edema and brain swelling, inflammation, and demyelination. Malformations occur when the central nervous system is affected during fetal life.

The remainder of this chapter will present the general aspects of the diseases of the nervous system according to anatomical sites. The salient features of the etiology, pathogenesis, clinical findings, diagnosis, and treatment of these clinicopathological diseases are described. The objective is to generalize about the clinical findings that are common or typical of different diseases affecting each of the major anatomical sites of the brain and spinal cord. Cerebral hypoxia and ischemia, hydrocephalus and cerebral edema are common to many diseases of the nervous system, and are described here.

Diffuse diseases of the brain*

CEREBRAL HYPOXIA

Cerebral hypoxia occurs when the supply of oxygen to the brain is reduced for any reason. An acute or chronic syndrome...
All forms of hypoxia, including anemic, anoxic, histotoxic, and stagnant forms cause some degree of cerebral hypoxia but signs referable to cerebral dysfunction occur only when the hypoxia is severe. The hypoxia of the brain may be secondary to a general systemic hypoxia or be caused by lesions restricted to the cranial cavity.

**Cerebral hypoxia secondary to general hypoxia**
- Poisoning by hydrocyanic acid or nitrite
- Acute heart failure in severe copper deficiency in cattle
- Anesthetic accidents
- Terminally in pneumonia, congestive heart failure
- During or at birth in foals, neonatal maladjustment syndrome in foals, or intrapartum hypoxia in calves and lambs due to prolonged parturition.

**Cerebral hypoxia secondary to intracranial lesion**
- In increased intracranial pressure
- In brain edema.

**PATHOGENESIS**
The central nervous system is extremely sensitive to hypoxia, and degeneration occurs if the deprivation is extreme and prolonged for more than a few minutes. The effects of the hypoxia vary with the speed of onset and with the severity. When the onset is sudden there is usually a transitory period during which excitation phenomena occur and this is followed by a period of loss of function. If recovery occurs, a second period of excitation usually develops as function returns. In more chronic cases the excitation phase is not observed, the signs being mainly those of loss of function. These signs include dullness and lethargy when deprivation is moderate, and unconsciousness when it is severe. All forms of nervous activity are depressed but the higher centers are more susceptible than medullary centers and the pattern of development of signs may suggest this.

**CLINICAL FINDINGS**
Acute and chronic syndromes occur depending on the severity of the hypoxia. Acute cerebral hypoxia is manifested by a sudden onset of signs referable to paralysis of all brain functions, including tetraparesis and unconsciousness. Muscle tremor, beginning around the head and spreading to the trunk and limbs, followed by recumbency, clonic convulsions and death or recovery after further clonic convulsions is the most common pattern, although affected animals may fall to the ground without premonitory signs. In chronic hypoxia there is lethargy, dullness, ataxia, weakness, blindness and in some cases muscle tremor or convulsions. In both acute and chronic hypoxia the signs of the primary disease will also be evident. Cerebral hypoxia of fetal calves is thought to be a cause of weakness and failure to suck after birth, leading to the eventual death of the calf from starvation. Such hypoxia can occur during the birth process, especially if it is difficult or delayed, or during late pregnancy.

**CLINICAL PATHOLOGY AND NECROPSY FINDINGS**
There is no distinctive clinical pathology or characteristic necropsy lesion other than those of the primary disease.

**DIFFERENTIAL DIAGNOSIS**
Clinically there is little to differentiate cerebral hypoxia from hypoglycemia or polioencephalomalacia in which similar signs occur. Irritation and paralytic signs follow one another in many poisonings including lead and arsenic and in most diffuse diseases of the brain including encephalitis and encephalomalacia. The differential diagnosis of cerebral hypoxia depends upon the detection of the cause of the hypoxia.

**TREATMENT**
An increase in oxygen delivery is essential and can usually only be provided by removing the causative agent. A respiratory stimulant (such as doxapram) may be advantageous in acute cases and artificial respiration may be necessary and effective.

**INCREASED INTRACRANIAL PRESSURE, CEREBRAL EDEMA, AND BRAIN SWELLING**
Diffuse cerebral edema and brain swelling usually occur acutely and cause a general increase in intracranial pressure. Cerebral edema is rarely a primary disease, but commonly an accompaniment of other diseases. Cerebral edema is commonly a transient phenomenon and may be fatal but complete recovery or recovery with residual nervous signs also occurs. It is manifested clinically by blindness, opisthotonos, muscle tremor, paralysis, and clonic convulsions.

**ETIOLOGY**
Diffuse cerebral edema and brain swelling may be **vasogenic**, when there is increased permeability of capillary endothelium, **cytotoxic** when all the elements of brain tissue, glia, neurons and endothelial cells undergo swelling. Causes include the following.

**Vasogenic edema**
- Brain abscess, neoplasm, hemorrhage, lead encephalopathy, purulent meningitis
- Minor edema after most traumatic injuries, in many encephalitides and many poisonings, including propylene glycol in the horse; probably contributes to the pathogenesis
- Accidental intracarotid injection of promazine in horses
- Leukoencephalomalacia in horses due to fumonisin consumption
- Septicemia in neonatal foals

**Cytotoxic edema**
- Hypoxia
- Polioencephalomalacia of ruminants (thiamine deficiency or sulfur toxicosis)
- Salt poisoning of swine.

**Interstitial edema**
- Hydrocephalus.

**PATHOGENESIS**
Cerebral edema and brain swelling This disease is potentially life-threatening because of the limited ability for accommodation of increased volume within the confines of the dura and the cranium. The central nervous system parenchyma does not possess a lymphatic system, and the interstitial space between cells, especially in the gray matter, is much narrower than in other tissues. When central nervous system edema develops, of necessity it largely accumulates within cells, although interstitial fluid will form if cells lyse or if the edema is severe.

Cerebral edema commonly occurs to some degree in all pathological states, whether degenerative or inflammatory, traumatic or neoplastic. Edema around chronic, focal lesions such as abscesses, parasitic cysts and primary or metastatic tumors in white matter often produces marked swelling. Cerebral hemispheric swelling compresses the underlying brainstem, flattening the rostral colliculi and distorting the aqueduct. As the swollen brain expands and fills the confines of the calvaria, some regions are prone to herniation. If this occurs, the accompanying blood vessels are likely to become occluded, which may result in hemorrhage or infarction. Commonly with brain swelling, the caudal lobe of the cerebellar vermis protrudes as a flattened lip over the medulla oblongata toward the foramen magnum.

In **vasogenic edema** the primary insult is to the wall of cerebral capillaries, allowing the escape of plasma fluid and proteins under the hydrostatic pressure of the circulation. The inciting vascular
injury may be brain or spinal cord trauma, vasculitis, a neoplasm or a cerebrovascular accident. Vasogenic edema affects predominantly the white matter, where fluid accumulates within the cytoplasm of astrocytes and spreads in the interstitial spaces. Vasogenic edema moves over very long distances and from one hemisphere to the other via the corpus callosum. A chronic epidural abscess involving the frontal lobe can produce sufficient brain swelling from vasogenic edema to induce herniation of the occipital cortex beneath the tentorium cerebelli.

Cytotoxic edema results from an injury to a glial cell that disturbs osmoregulation of that cell by depletion of energy stores and failure of energy-dependent ion pumps. This leads to cell swelling with fluid, and differs from edema in other tissues in which fluid accumulation is interstitial. Cytotoxic edema reflects a specific cellular insult and may result from ischemia or hypoxia, nutritional deficiency, an intoxication or an inherited metabolic abnormality. Brain swelling from cytotoxic edema is less dramatic than that seen in vasogenic edema. It may affect just the gray matter, just the white matter, or both.

The extracellular fluid volume in vasogenic edema is increased by the edema fluid, which is a plasma filtrate containing plasma protein. In cytotoxic edema it is the cellular elements themselves that increase in size. In hypoxia this is because of failure of the adenosine triphosphate (ATP)-dependent sodium pump within the cells. As a result sodium accumulates within the cells and water follows to maintain osmotic equilibrium. In polioencephalomalacia and salt poisoning the edema of the brain is primary. In salt poisoning in pigs there is an increase in concentration of cations in brain tissue with a sudden passage of water into the brain to maintain osmotic equilibrium. The cause of the edema in polioencephalomalacia of ruminants, associated with a thiamin inadequacy, is unknown. When promazine is injected accidentally into the carotid artery of the horse it produces a vasogenic edema and infarction generally, but especially in the thalamus and corpora quadrigemina on the injected side. The vasogenic edema surrounding an abscess is localized and is not evident in the white matter.

Cerebral edema and cerebellar herniation as described in neonatal foals, 3, 12-24 hours later by the dexamethasone, also is (apart from the primary cause of the disease. Mannitol at 2 g/kg BW and dexamethasone at 1 mg/kg BW, both intravenously, are recommended. The mannitol is given intravenously as a 20% solution followed 3 hours later by the dexamethasone, also intravenously. Diuretics usually produce tissue dehydration too slowly to be of much value in acute cases, but they may be of value as an adjunct to hypertonic solutions or in early or chronic cases. The removal of CSF from the cisterna magna in an attempt to provide relief may cause complications. In some cases the removal of 25–75 mL of CSF provides some temporary relief but the condition becomes worse later because portions of the swollen brain herniate into the foramen magnum. There is no published information available on how much fluid can be safely removed and recommendations cannot therefore be made.

Necropsy Findings

Microscopically the gyri are flattened and the foramen magnum is partially herniated into the foramen magnum with consequent distortion of its caudal aspect. The brain has a soft, swollen appearance and tends to sag over the edges of the cranium when the top has been removed. Caudal portions of the occipital lobes herniate ventral to the tentorium cerebelli.

Differential Diagnosis

Diffuse brain edema causes a syndrome not unlike that of encephalitis although there are fewer irritation phenomena. Differentiation from encephalomalacia and vitamin A deficiency may be difficult if the history does not give a clue to the cause of the disease. Metabolic diseases, particularly pregnancy toxemia, hypomagnesemic tetany of calves and lactation tetany, resemble it closely, as do some cases of acute ruminal impaction. In the history of each of these diseases there are distinguishing features that aid in making a tentative diagnosis. Some of the poisonings, particularly lead, organic mercurials and arsenicals and enterotoxemia associated with Clostridium perfringens type D produce similar nervous signs and cut edema of swine may be mistaken for diffuse cerebral edema.

Treatment

Decompression of the brain is desirable in acute edema. The treatment will depend in part on the cause; the edema associated with polioencephalomalacia will respond to early treatment with thiamin. In general terms, edema of the brain responds to parenteral treatment with hypertonic solutions and corticosteroids. Hypertonic solutions are most applicable to cytotoxic edema and corticosteroids to vasogenic edema. This is in addition to treatment for the primary cause of the disease. Mannitol at 2 g/kg BW and dexamethasone at 1 mg/kg BW, both intravenously, are recommended. The mannitol is given intravenously as a 20% solution followed 3 hours later by the dexamethasone, also intravenously. Diuretics usually produce tissue dehydration too slowly to be of much value in acute cases, but they may be of value as an adjunct to hypertonic solutions or in early or chronic cases. The removal of CSF from the cisterna magna in an attempt to provide relief may cause complications. In some cases the removal of 25–75 mL of CSF provides some temporary relief but the condition becomes worse later because portions of the swollen brain herniate into the foramen magnum. There is no published information available on how much fluid can be safely removed and recommendations cannot therefore be made.

Clinical Pathology

Clinicopathological observations will depend on the specific disease causing the edema.
HYDROCEPHALUS
Obstructive hydrocephalus may be congenital or acquired and is manifested in both cases by a syndrome referable to a general increase in intracranial pressure. Irritation signs of mania, head-pressing, muscle tremor and convulsions occur when the onset is rapid, and signs of paralysis including dullness, blindness and muscular weakness are present when the increased pressure develops slowly.

ETIOLOGY
Obstructive hydrocephalus may be congenital or acquired but in both instances it is due to defective drainage or absorption of CSF. In the congenital disease there is an embryological defect in the drainage canals and foramina between the individual ventricles or between the ventricles and the subarachnoid space, or in the absorptive mechanism, the arachnoid villi.

Congenital hydrocephalus
Causes are:
- Alone, with lateral narrowing of the mesencephalon
- Inherited defects of Hereford, Holstein, Ayrshire and Jersey cattle
- Inherited combined defects with chondrodysplasia, or in white Shorthorn cattle combined with hydrocephalus, microphthalmia and retinal dysplasia
- Virus infections of the fetus suggest themselves as possible causes of embryological defects in the drainage system, but there are no verified examples of this. The cavitation of brain tissue and subsequent accumulation of fluid, hydranencephaly, which occurs after infection with bluetongue virus in lambs and Akabane virus in calves, is compensatory, not obstructive
- Vitamin A deficiency may contribute
- Other occurrences, sometimes at high levels of prevalence, but without known cause.

Acquired hydrocephalus
Causes include:
- Hypovitaminosis A in young growing calves causing impaired absorption of fluid by the arachnoid villi
- Cholesteatoma in choroid plexuses of the lateral ventricles in the horse. These may produce an acute, transient hydrocephalus on a number of occasions before the tumor reaches sufficient size to cause permanent obstruction
- Other tumor or chronic inflammatory lesion obstructing drainage from the lateral ventricles.

PATHOGENESIS
Increased intracranial pressure in the fetus and before the syndromes of the skull have fused causes hydrocephalus with enlargement of the cranium. After fusion of the suture lines the skull acts as a rigid container and an increase in the volume of its contents increases intracranial pressure. Although the increase in volume of the contents may be caused by the development of a local lesion such as an abscess, tumor, hematoma or cestode cyst, which interferes with drainage of the CSF, the more common lesion is a congenital defect of CSF drainage.

Clinical and pathological hydrocephalus has been produced experimentally in animals by creating granulomatous meningitis. The clinical signs included depression, stiffness of gait, recumbency and opisthotonus with paddling convulsions. The general effects in all cases are the same, the only difference being that local lesions may produce localizing signs as well as signs of increased intracranial pressure. These latter signs are caused by compression atrophy of nervous tissue and ischemic anoxia due to compression of blood vessels and impairment of blood supply to the brain.

In congenital hydrocephalus the signs observed are usually those of paralysis of function, while acquired hydrocephalus, being more acute, is usually manifested first by irritation phenomena followed by signs of paralysis. Edema of the optic papilla is a sign of increased intracranial pressure and may be detected ophthalmoscopically. Bradycardia occurs inconsistently and cannot be considered to be diagnostic.

CLINICAL FINDINGS
In acquired hydrocephalus there is, in most cases, a gradual onset of general paresis. Initially there is depression, disinclination to move, central blindness, an expressionless stare and a lack of precision in acquired movements. A stage of somnolence follows and is most marked in horses. The animal stands with half-closed eyes, lowered head and a vacant expression and often leans against or supports itself upon some solid object. Chewing is slow, intermittent and incomplete and animals are often observed standing with food hanging from their mouths. The reaction to cutaneous stimulation is reduced, and abnormal postures are frequently adopted. Frequent stumbling, faulty placement of the feet and incoordination are evidenced when the animal moves, and circling may occur in some cases. Bradycardia and cardiac arrhythmia have been observed.

Although the emphasis is on depression and paresis, signs of brain irritation may occur, particularly in the early stages. These signs often occur in isolated episodes during which a wild expression, charging, head-pressing, circling, tremor and convulsions appear. These episodes may be separated by quite long intervals, sometimes of several weeks’ duration. In vitamin A deficiency in calves blindness and papilledema are the early signs and an acute convulsive stage occurs terminally.

Cerebrally affected animals are usually alive at birth but are unable to stand and most die within 48 hours. The cranium is sometimes domed, the eyes protrude and nystagmus is often evident. Meningocele is an infrequent accompaniment.

CLINICAL PATHOLOGY
Examination of the composition and pressure of the CSF will be of value. The fluid is usually normal biochemically and cytologically but the pressure is increased. A marked increase in serum muscle enzyme activity has been observed in calves with congenital hydrocephalus, due probably to an accompanying muscular dystrophy. Convulsions, if they occur, may contribute to this increase.

NECROPSY FINDINGS
The cranium may be enlarged and soft in congenital hydrocephalus. The ventricles are distended with CSF under pressure and the overlying cerebral tissue is thinned if the pressure has been present for some time.

DIFFERENTIAL DIAGNOSIS
Congenital hydrocephalus resembles vitamin A deficiency in newborn pigs, toxoplasmosis and hydranencephaly if there is no distortion of the cranium. Acquired hydrocephalus needs to be differentiated from other diffuse diseases of the brain, including encephalitis and encephalomalacia, and from hepatic dystrophies, which resemble it very closely. In these latter diseases there may be other signs of diagnostic value, including fever in encephalitis and jaundice in hepatic dystrophy. In most cases it is necessary to depend largely on the history and recognition of individual disease entities.

ENCEPHALITIS
Encephalitis is, by definition, inflammation of the brain but in general usage it includes those diseases in which inflammatory lesions occur in the brain, whether there is inflammation of the nervous tissue or primarily of the vessel walls. Clinically, encephalitis is characterized initially...
by signs of involuntary movements, followed by signs caused by loss of nervous function. The meninges and spinal cord may be involved in an encephalitis, causing varying degrees of meningoencephalomyelitis.

ETIOLOGY
Many encephalitides of large animals are associated with viruses but other infectious agents are also common. Some causes are as follows.

All species
- Viral infections – rabies, pseudorabies, Japanese B encephalitis, West Nile virus encephalomyelitis
- Bacterial infections of neonatal farm animals
- Toxoplasmosis, which is not a common cause in any species
- Sarcocystosis
- Verminous encephalomyelitis – migration of larvae of parasitic species that normally have a somatic migration route, e.g. *Micronema deletrix*, *Setaria* spp.
- *Paraelaphostrongylus tenuis*

Cattle
- Bovine spongiform encephalopathy
- Viral infections – bovine malignant catarrh, sporadic bovine encephalomyelitis and bovine herpes virus
- Bacterial infections including *Listeria monocytogenes*, *Histophilus somni* (formerly *Haemophilus somni*)
- *heartwater*, *clostridial infections following dehorning of calves*
- Migration of *Hypoderma bovis* occasionally to brain and spinal cord

Sheep
- Scrapie
- Viral infections – loping ill, visna (associated with Maedi-visna virus)
- *Thrombotic meningoencephalitis associated with H. somni* (formerly *Histophilus ovis*) in lambs
- *Bacterial meningoencephalitis in lambs 2–4 weeks of age*
- Migration of *Oestrus ovis*

Goats
- Scrapie
- Caprine arthritis–encephalitis virus

New World camels
- *Bacterial infection due to L. monocytogenes*

Pigs
- Bacterial infections – as part of systemic infections with *Salmonella* and *Escherichia* spp., rarely *L. monocytogenes*
- Viral infections – hog cholera, African swine fever, encephalomyocarditis, swine vesicular disease, hemagglutinating encephalomyelitis virus, porcine encephalomyelitis virus

Horses
- Viral infections – infectious equine encephalomyelitis, Borna disease, equine herpes virus, equine infectious anemia, eastern, western and West Nile equine encephalomyelitides, rarely loupiloung ill virus
- *Protozoal encephalomyelitis*
- *Verminous encephalomyelitis due to Strangles vulgaris in horses and Droschia megastoma. Angiostrongylus cantonensis*, which normally migrates through the central nervous system of the rat, has been found as a cause of verminous encephalomyelitis in foals

PATHOGENESIS
Compared to other extraneural tissues, the inflammatory response mounted by the nervous system is unique. The central nervous system is in a sequestered and immunologically dormant state within the body. The capillary endothelial blood–brain barrier restricts free access by blood constituents. The central nervous system lacks specialized dendritic antigen-presenting cells, and the intrinsic expression by central nervous system cells of major histocompatibility complex molecules, especially class II, is low. There is no lymphatic system within nervous tissue, but cells and antigens within the central nervous system drain into the circulation and to the cervical lymph nodes.

The central nervous system has unique populations of cells consisting of parenchymal cells, which are neurons, and neuroglia. The neuroglia are supporting cells and are subdivided into macroglia and microglia: the macroglia are astrocytes and oligodendrocytes; the third glial cell type is a microglial cell. The brain and spinal cord are enclosed by the meninges (dura, arachnoid and pia), which provide protection, a compartment for the CSF circulation (the subarachnoid space), support for blood vessels and a sheath for the cranial and spinal nerves. Within the brain and spinal cord the ventricular and central canal, which are lined by *ependymal cells* and the choroidplexuses, which produce the CSF. Circulation of the CSF moves from the lateral, third and fourth ventricles into the central canal or through lateral apertures at the cerebellomedullary angle into the subarachnoid space of the brain. CSF in the subarachnoid space drains via specialized arachnoid granulations into intracranial venous sinuses, with some draining into venous plexuses associated with cranial and spinal nerves. CSF may also cross the ventricular surface into the adjacent parenchyma.

The histological characteristics of central nervous system inflammation are:
- Perivascular cuffing
- *Gliosis*
- Neuronal satellitosis and *neuronophagia*.

A perivascular compartment, actual or potential, exists around all central nervous system arteries, arterioles, venules and veins. A characteristic feature of central nervous system inflammation is perivascular cuffing, the accumulation of leukocytes of one or multiple types in the perivascular space. All perivascular cuffing results in vasculitis of some degree. In bacterial diseases, polymorphonuclear cells predominate with a minor component of mononuclear cells. In general, viral diseases are characterized by lymphocyte-rich cells with some plasma cells and monocytes; some arbovirus infections cause a polymorphonuclear cell response. In immunemediated diseases, there are mixtures of polymorphonuclear and mononuclear cells. In lymphocytic meningoencephalitis, vascular occlusion precludes the development of cuffing around injured vessels.

*Gliosis* is the increased prominence of glial cells, resulting from cytoplasmic swelling and the acquisition of more cell processes, from cell proliferation, or both. Either of the macroglia (oligodendrocytes or astrocytes) or microglia may participate in gliosis.

*Neuronal satellitosis* occurs when oligodendrocytes react and proliferate in response to degenerating neurons which may be infected by a virus.

*Neuronophagia* is the progressive degeneration of the neuron characterized by its piecemeal division and phagocytosis, eventually leaving a dense nodule of glial cells and fragments of the former neuron. Details of the form, functions and roles of astrocytes in neurological disease have been reviewed.

*Primary demyelination* is characteristic of only a small number of inflammatory neurological diseases and is associated with only a few viruses. The inflammatory neuraxial diseases of large animals include visna in sheep and caprine arthritis–encephalitis. The demyelinating process may be initiated directly by the infectious agent alone or by an immunological response initiated by the agent.

With the exception of the viruses of bovine malignant catarrh and equine herpesvirus 1, which exert their effects principally on the vasculature, those viruses that cause encephalitis do so by invasion of cellular elements, usually the neurons, and cause initial stimulation and then death of the cells. Those bacteria that
cause diffuse encephalitis also exert their effects primarily on vascular endothelium. *L. monocytogenes* does so by the formation of microabscesses. In some diseases, such as meningoencephalitis in cattle associated with *H. somni*, the lesions may be present in the brain and throughout the spinal cord.9

**Entrance of the viruses** into the nervous tissue occurs in several ways. Normally the blood–brain barrier is an effective filtering agent but when there is damage to the endothelium infection readily occurs. The synergistic relationship between the rickettsias of tick-borne fever and the virus of loping ill probably has this basis. Entry may also occur by progression of the agent up a peripheral nerve trunk, as occurs with the viruses of rabies and pseudorabies and with *L. monocytogenes*. Entry via the olfactory nerves is also possible.

**The clinical signs** of encephalitis are usually referable to a general stimulatory or lethal effect on neurons in the brain. This may be in part due to the general effect of inflammatory edema and in part to the direct effects of the agent on nerve cells. In any particular case one or other of these factors may predominate but the tissue damage and therefore the signs are generalized. Clinical signs are often diverse and can be acute or chronic, localized or diffuse, and progressive or reversible. Because of diffuse inflammation in encephalitis, the clinical signs are commonly multifocal and asymmetric. This is not the case in listeriosis, in which damage is usually localized in the pons–medulla. Localizing signs may appear in the early stages of generalized encephalitis and remain as residual defects during the stage of convalescence. In calves with thromboembolic meningoencephalitis due to *H. somni*, prolonged recumbency may be associated with widespread lesions of the spinal cord.Visna is a demyelinating encephalitis, and caprine leukencephalomyelitis is both demyelinating and inflammatory and also invades other tissues including joints and lung.

**In verminous encephalomyelitis,** destruction of nervous tissue may occur in many parts of the brain and in general the severity of the signs depends upon the size and mobility of the parasites and the route of entry. One exception to this generalization is the experimental 'visceral larva migrans' produced by *Toxocara canis* in pigs when the nervous signs occur at a time when lesions in most other organs are healing. The signs are apparently provoked by a reaction of the host to static larvae rather than trauma due to migration. Nematoles not resident in nervous tissues may cause nervous signs due possibly to allergy or to the formation of toxins.

**CLINICAL FINDINGS**

Because the encephalitides are associated with infectious agents they are often accompanied by fever, anorexia, depression and increased heart rate. This is not the case in the very chronic diseases such as scrapie and bovine spongiform encephalopathy. In those diseases associated with agents that are not truly neurotropic, there are characteristic signs, which are not described here.

The clinical findings that can occur in encephalitis are combinations of:

- **Subtle to marked changes of behavior**
- **Depression**
- **Seizures**
- **Blindness**
- **Compulsive walking**
- **Leaning on walls or fences**
- **Circling**
- **Ataxia.**

Bacterial meningoencephalitis in lambs 2–4 weeks of age is characterized by lack of suck reflex, weakness, altered gait and depression extending to stupor, but hypersensitivity to auditory and tactile stimuli.6 Opposinotonus is common during the terminal stages.

There may be an initial period of excitement or mania. The animal is easily startled and responds excessively to normal stimuli. It may exhibit viciousness and uncontrolled activity including blind charging, belowing, kicking and pawing. Self-mutilation may occur in diseases such as pseudorabies. Mental depression, including head-pressing, may occur between episodes. Involuntary movements are variable in their occurrence or may not appear at all. When they do occur they include convulsions, usually clonic, and may be accompanied by nystagmus, champing of the jaws, excessive frothy salivation and muscle tremor, especially of the face and limbs. In cattle with malignant catarrhal fever, there is severe depression for a few days followed by the onset of tremors associated with the terminal encephalitis. Unusual irritation phenomena are the paresthesia and hyperesthesia of pseudorabies and scrapie.

**Signs caused by loss of nervous function** follow and may be the only signs in some instances. Excessive drooling and pharyngeal paralysis are common in rabies. In horses with equine encephalomyelitis, feed may be left hanging from the mouth, although swallowing may not be impaired. The loss of function varies in degree from paresis with knuckling at the lower limb joints, to spasticity of the limbs with resultant ataxia, to weakness and recumbency. Recumbency and inability to rise may be the first clinical finding encountered as in many cases of meningoencephalitis associated with *H. somni*. Hypermetria, a staggering gait and apprehensiveness progressing to belligerency may occur in a disease such as bovine spongiform encephalopathy.

Clinical signs referable to certain anatomical sites and pathways of the brain and spinal cord are manifested by deviation of the head, walking in circles, abnormalities of posture, ataxia and incoordination but these are more commonly residual signs after recovery from the acute stages. Progressive ascending spinal cord paralysis, in which the loss of sensation and weakness occur initially in the hindlimbs followed by weakness in the forelimbs, occurs commonly in rabies. Residual lesions affecting the cranial nerves do not commonly occur in the encephalitides, except in listeriosis and protozoal encephalitis of horses, both infections predominating in the caudal brainstem.

An acute hemorrhagic necrotizing encephalitis following dehorning calves has been described.2 Affected calves were found dead or moribund within a few days following dehorning using a gouge. A secondary clostridial infection was suspected.

In the horse with cerebral nematodiasis due to *S. vulgaris* the clinical signs are referable to migration of the parasite in the thalamus, brainstem and cerebellum. There is incoordination, leaning and head-pressing, dysmetria, intermittent clonic convulsions, unilateral or bilateral blindness and paralysis of some cranial nerves. The onset may be gradual or sudden. The clinical diagnosis is extremely difficult because examination of CSF and hematology are of limited value. A pathological diagnosis is necessary. In foals with neural angiostrongylosis, tetraparesis was the end result of progressive and multifocal neurological disease.7

**CLINICAL PATHOLOGY**

Clinical pathology may be of considerable assistance in the diagnosis of encephalitis but the techniques used are for the most part specific to the individual diseases.

**Hemogram**

In the horse, complete and differential blood counts and serum chemistry profiles are recommended for most neurological cases.

**Serology**

Acute and convalescent sera can be submitted when a specific infectious disease is suspected for which a serologic diagnosis is possible.
Cerebrospinal fluid

Laboratory examination of CSF for cellular content and pathogens may also be indicated. In bacterial meningoencephalitis of young lambs, analysis of CSF obtained from the lumbosacral space reveals a highly significant increase in protein concentration with neutrophilic pleocytosis.5

NECROPSY FINDINGS

In some of the commonly occurring encephalitides there are no gross lesions of the brain apart from those that occur in other body systems and that are typical of the specific disease. In other cases, on transverse section of the brain, extensive areas of hemorrhagic necrosis may be visible, as in meningoencephalitis in cattle due to *H. somnis*. Histological lesions vary with the type and mode of action of the causative agent. Material for laboratory diagnosis should include the fixed brain and portions of fresh brain material for culture and for transmission experiments.

DIFFERENTIAL DIAGNOSIS

The diagnosis of encephalitis cannot depend entirely on the recognition of the typical syndrome because similar syndromes may be caused by many other brain diseases. Acute cerebral edema and focal space-occupying lesions of the cranial cavity, and a number of poisonings, including salt, lead, arsenic, mercury, rotenone and chlorinated hydrocarbons all cause similar syndromes, as do hypovitaminosis A, hypoglycemia, encephalomalacia and meningitis.

Fever is common in encephalitis but is not usually present in rables, scrapie, or bovine spongiform encephalopathy; but it may occur in the noninflammatory diseases if convulsions are severe.

Generally, the clinical diagnosis rests upon the recognition of the specific encephalitides and the elimination of the other possible causes on the basis of the history and clinical pathology, especially in poisonings, and on clinical findings characteristic of the particular disease. In many cases a definite diagnosis can only be made on necropsy. For differentiation of the specific encephalitides reference should be made to the diseases listed under Etiology, above.

Infestation with nematode larvae causes a great variety of signs depending on the number of invading larvae and the amount and location of the damage.

TREATMENT

Specific treatments are dealt with under each disease. Antimicrobials are indicated for bacterial meningoencephalomyelitis. Generally the aim should be to provide supportive treatment by intravenous fluid and electrolyte therapy or stomach tube feeding during the acute phase. Sedation during the excitement stage may prevent the animal from injuring itself, and nervous system stimulants during the period of depression may maintain life through the critical phase. Although there is an increase in intracranial pressure, the removal of CSF is contraindicated because of the deleterious effects of the procedure on other parts of the brain.

REFERENCES

ENCEPHALOMALACIA OR THE DEGENERATIVE DISEASES OF THE CENTRAL NERVOUS SYSTEM

The degenerative diseases of the brain are grouped together under the name encephalomalacia. By definition encephalomalacia means softening of the brain. It is used here to include all degenerative changes. Leukoencephalomalacia and polioencephalomalacia refer to softening of the white and gray matter respectively.

Abiotrophy is the premature degeneration of neurons due to an inborn metabolic error of development and excludes exogenous insults of neurons. The underlying cellular defect in most abiotrophies is inherited. The syndrome produced in most degenerative diseases of the nervous system is essentially one of loss of function.

ETOIOLOGY

Some indication of the diversity of causes of encephalomalacia and degenerative diseases of the nervous system can be appreciated from the examples which follow but many sporadic cases occur in which the cause cannot be defined.

All species
- Hepatic encephalopathy thought to be due to high blood levels of ammonia associated with advanced liver disease.1 This is recorded in experimental pyrrolizidine alkaloid poisoning in sheep, in hepatic arteriovenous anomaly and thrombosis of the portal vein in the horse. Congenital portocaval shunts are also a cause
- Abiotrophy involving multisystem degenerations in the nervous system as focal or diffuse lesions involving the axons and myelin of neuronal processes.2 These include a multifocal encephalopathy in the Simmental breed of cattle in New Zealand and Australia,3 and progressive myeloencephalopathy in Brown Swiss cattle, known as ‘weavers’ because of their ataxic gait (see below and Chapter on Inherited Defects)4
- Poisoning by organic mercurials and, in some instances, lead; possibly also selenium poisoning: a bilateral multifocal cerebrospinal poliomala cia of sheep in Ghana
- Cerebrovascular disorders corresponding to the main categories in humans are observed in animals, but their occurrence is chiefly in pigs and their clinical importance is minor
- Congenital hypomyelinogenesis and dysmyelinogenesis are recorded in lambs (hairy shakers), piglets (myoclonia congenita) and calves (hypomyelinogenesis congenita). All are associated with viral infections in utero. Equine herpesvirus-1 infections in horses cause ischemic infarcts
- Cerebellar cortical abiotrophy in calves and lambs.2-4

Ruminants
- Bovine spongiform encephalopathy
- Plant poisons, e.g. *Astragalus* spp., *Oxytrops* spp., *Swainsona* spp., *Vicia* spp., *Kochia* scoparia
- Focal symmetrical encephalomalacia of sheep, thought to be a residual lesion after intoxication with *Clostridium perfringens* type D toxin
- Polioencephalomalacia caused by thiamin inadequacy in cattle and sheep and sulfur toxicosis in cattle; poliomala cia of sheep caused possibly by an antimetabolite of nicotinic acid
- Progressive spinal myelopathy of Murray Grey cattle in Australia
- Spongiform encephalopathy in newborn polled Hereford calves similar to maple syrup urine disease
- Neuronal dystrophy in Suffolk sheep
- Shakers in horned Hereford calves associated with neuronal cell body chromatolysis
- The abiotrophic lysosomal storage diseases – progressive ataxia of Charolais cattle, mannosidosis, ganglosidosis, globoid cell leukodystrophy of sheep
- The inherited defect of Brown Swiss cattle known as ‘weavers’, and presented elsewhere, is a degenerative myeloencephalopathy
- Swayback and enzootic ataxia due to nutritional deficiency of copper in lambs
- Prolonged parturition of calves causing cerebral hypoxia and the weak calf syndrome.
Infarcts. Gas-anesthesia-related neurological disease occurs in animals that have been deprived of oxygen for more than 5 minutes.

The hypoxia is lethal to neurons and upon recovery from the anesthetic affected animals are blind and seizures may occur. The typical lesion consists of widespread neuronal damage. Post-anesthetic hemorrhagic myelopathy and postanesthetic cerebral necrosis in horses are typical examples. Hypoglycemia occurs in neonates deprived of milk and in acetonemia and pregnancy toxemia and clinical signs of lethargy, dullness progressing to weakness, seizures and coma have been attributed to hypoglycemia. However, there are no studies of the central nervous system in farm animals with hypoglycemia and the effects, if any, on the nervous tissue are unknown.

**Intoxications and toxic-infectious diseases**

A large number of poisonous substances including poisonous plants, heavy metals (lead, arsenic, mercury), salt poisoning, farm chemicals, antifreeze, herbicides and insecticides can directly affect the nervous system when ingested by animals. They result in varying degrees of edema of the brain, degeneration of white and gray matter and hemorrhage of both the central and peripheral nervous system. Toxic-infectious diseases such as edema disease of swine and focal symmetrical encephalomalacia of sheep are examples of endotoxins and exotoxins produced by bacterial infections which have a direct effect on the nervous system resulting in encephalomalacia.

**Metabolic and circulatory disorders**

Several nutritional deficiencies of farm animals can result in neurological disease:

- **Vitamin A deficiency** affects bone growth, particularly remodeling of the optic nerve tracts, and CSF absorption. The elevated CSF pressure and constriction of the optic nerve tracts results in edema of the optic disc and wallerian-type degeneration of the optic nerve resulting in blindness.

- **Copper deficiency** in pregnant ewes can result in swayback and enzootic ataxia of the lambs. Copper is an integral element in several enzyme systems such as ceruloplasmin and l-lysyl oxidase, and copper deficiency affects several organ systems. The principal defect in swayback appears to be one of defective myelination probably caused by interference with phospholipid formation. However, some lesions in the newborn are more extensive, and show cavitation with loss of axons and neurons rather than simply demyelination. In the brain, there is a progressive gelatious transformation of the white matter, ending in cavitation that resembles porencephaly or hydranencephaly. In the spinal cord the lesions are bilateral and it is suggested that the copper deficiency has a primary axonopathic effect.

- **Thiamine deficiency** in ruminants can result in polioencephalomalacia or cerebrocortical necrosis. Thiamine, mainly as thiamine diphosphate (pyrophosphate), has an important role as a coenzyme in carbohydrate metabolism especially the pentose pathway. Diffuse encephalopathy may occur characterized by brain edema and swelling, resulting in flattening of the gyri, tentorial herniation and coning of the cerebellar vermis. Bilateral areas of cerebral cortical laminar necrosis are widespread.

**Hereditary, familial, and idiopathic degenerative diseases**

A large number of neurological diseases of farm animals are characterized by abnormalities of central myelinogenesis. In most instances the underlying abnormality directly or indirectly affects the oligodendrocyte and is reflected in the production of central nervous system myelin of diminished quantity or quality or both. Many of these are inherited and are manifest from or shortly after birth. They include leukodystrophies, hypomyelinogenesis, spongy degeneration, and related disorders. Neuronal atrophy, motor neuron diseases, neuronal dystrophy and degenerative encephalomyelopathy of horses and cattle are included in this group.

**Polioencephalomalacia and leukoencephalomalacia**

Polioencephalomalacia appears to be, in some cases at least, a consequence of acute edematous swelling of the brain and cortical ischemia. The pathogenesis of leukoencephalomalacia appears to be related to vasogenic edema as a result of cardiovascular dysfunction and an inability to regulate cerebral blood flow. Whether the lesion is in the gray matter (polioencephalomalacia) or in the white matter (leukoencephalomalacia), the syndrome is largely one of loss of function although as might be expected irritation signs are more likely to occur when the gray matter is damaged.

**Clinical findings**

Weakness of all four limbs is accompanied by:

- Dullness or somnolence
- Blindness
Ataxia
- Head-pressing
- Circling
- Terminal coma.

In the early stages, particularly in ruminant polioencephalomalacia, there are involuntary signs including muscle tremor, opisthotonus, nystagmus, and convulsions.

In equine leukoencephalomalacia, which may occur in outbreaks, initial signs include anorexia and depression.3 In the neurotoxic form, which is most common, the anorexia and depression progresses to ataxia, circling, apparent blindness, head-pressing, hyperesthesia, agitation, delirium, recumbency, seizures, and death. An early and consistent sign in affected horses is reduced proprioception of the tongue, manifest as delayed retraction of the tongue to the buccal cavity after the tongue has been extended.10 In the hepatotoxicosis form, clinical findings include icterus, swelling of the lips and nose, petechiation, abdominal breathing and cyanosis. Horses with either syndrome may be found dead without any premonitory signs.

In many of the leukoencephalomalacias, the course may be one of gradual progression of signs, or more commonly a level of abnormality is reached and maintained for a long period, often necessitating euthanasia of the animal. For example, equine degenerative myeloencephalopathy is a diffuse degenerative disease of the equine spinal cords and caudal portion of the brainstem and primarily affects young horses. There is an insidious onset of symmetrical spasticity, ataxia, and paresis. Clinical signs may progress slowly to stabilize for long periods. All four limbs are affected, but the pelvic limbs are commonly more severely affected than the thoracic limbs. In some cases of trauma to the brain, clinical evidence of injury to the brain may be delayed for a few days because of the force required to cause contusion. There is maintenance of structure and function, but hemispheric lesions may be visible. The important lesions are described under each of the specific diseases mentioned above under Etiology.

**Necropsy Findings**

Gross lesions including areas of softening, cavitation and laminar necrosis of the cortex may be visible. The important lesions are described under each of the specific diseases.

**Treatment**

The prognosis depends on the nature of the lesion. Early cases of thiamine-deficiency-induced polioencephalomalacia can recover completely if treated with adequate levels of thiamin. Encephalomalacia due to sulfur-induced polioencephalomalacia and lead poisoning is more difficult to treat. Young calves with acquired acute myelitis associated with equine herpesvirus-1 infection can make complete recoveries.

**References**

**DIFFERENTIAL DIAGNOSIS**

The syndromes produced by encephalomalacia resemble very closely those caused by most lesions that elevate intracranial pressure. The onset is quite sudden and there is depression of consciousness and loss of motor function. One major difference is that the lesions tend to be nonprogressive and affected animals may continue to survive in an impaired state for long periods.
but loss of vascular integrity, resulting in hemorrhage into the parenchyma and meninges relative to the point of impact. Bony deformation or fracture of the calvaria result in two different kinds of focal lesions:

- Direct (coup) contusions immediately below the impact site
- Indirect (contrecoup) contusions to the brain at the opposite point of the skull. Contrecoup hemorrhages result from tearing of leptomeningeal and parenchymal blood vessels.

**Laceration**

The most severe contusion is laceration where the central nervous system tissue is physically torn or disrupted by bony structures lining the cranium or by penetrating objects such as bone fragments. Focal meningeal hemorrhage is a common sequel to severe head injury. Subdural hematomas usually follow disruption of bridging cerebral veins that drain into the dural venous sinuses but subarachnoid hemorrhages are more common. The importance of these hemorrhages is that they develop into space-occupying masses that indent and compress the underlying brain. Progressive enlargement of the hematoma can result in secondary effects such as severe, widespread brain edema, areas of ischemia, herniations, midline shift, and lethal brainstem compression.

In birth injuries the lesion is principally one of hemorrhage subdurally and under the arachnoid.

**Experimental traumatic cranioencephalocerebral missile injury**

Traumatic insult of the brains of sheep with a .22 caliber firearm results in a primary hemorrhagic wound track with induced bone fragments and portions of muscle and skin. There is crushing and laceration of tissues during missile penetration, secondary tracks due to bone and bullet fragments, widely distributed stretch injuries to blood vessels, nerve fibers and neurons as a consequence of the radial forces of the temporary cavity that develops as a bullet penetrates tissue, marked subarachnoid and intraventricular hemorrhage, and distortion and displacement of the brain. The lesions are consistently severe and rapidly fatal.

**CLINICAL FINDINGS**

The syndrome usually follows the pattern of greatest severity initially with recovery occurring quickly but incompletely to a point where a residual defect is evident, this defect persisting unchanged for a long period and often permanently. This failure to improve or worsen after the initial phase is a characteristic of traumatic injury.

With severe injury there is cerebral shock in which the animal falls unconscious with or without a transient clonic convolution. Consciousness may never be regained but in animals that recover it returns in from a few minutes up to several hours. During the period of unconsciousness, clinical examination reveals dilatation of the pupils, absence of the eye preservation and pupillary light reflexes, and a slow, irregular respiration, the irregularity being phasic in many cases. There may be evidence of bleeding from the nose and ears and palpation of the cranium may reveal a site of injury. Residual signs vary a great deal, blindness is present if the optic cortex is damaged; hemiplegia may be associated with lesions in the midbrain; traumatic epilepsy may occur with lesions in the motor cortex.

**Fracture of the petrous temporal bone** is a classic injury in horses caused by rearing and falling over backwards. Both the facial and the vestibular nerves are likely to be damaged so that at first the animal may be unable to stand and there may be blood from the ear and nostril of the affected side. When the animal does stand the head is rotated with the damaged side down. There may be nystagmus, especially early in the course of the disease. The ear, eyelid, and lip on the affected side are also paralyzed and sag. Ataxia with a tendency to fall is common. Some improvement occurs in the subsequent 2 or 3 weeks as the horse compensates for the deficit, but there is rarely permanent recovery. An identical syndrome is recorded in horses in which there has been a stress fracture of the petrous temporal bone resulting from a pre-existing inflammation of the bone. The onset of signs is acute but unassociated with trauma.

**Fracture of the basioccipital** and/or basioccipital and/or basioccipital bones is also common. These fractures can seriously damage the jugular vein, carotid artery and glossopharyngeal, hypoglossal and vagus nerves. The cavernous sinus and the basilar artery may also be damaged and lead to massive hemorrhage within the cranium. Large vessels in the area are easily damaged by fragments of the fractured bones, causing fatal hemorrhage. A midline fracture of the frontal bones can also have this effect.

Other signs of severe trauma to the brain include opisthotonus with blindness and nystagnus and, if the brainstem has been damaged, quadriplegia. There may also be localizing signs, including head rotation, circling and falling backwards. Less common manifestations of resulting hemorrhage include bleeding into the retropharyngeal area, which may cause pressure on guttural pouches and the airways and lead to asphyxia. Bleeding may take place into the guttural pouches themselves.

Newborn lambs affected by birth injury to the brain are mostly dead at birth, or die soon afterwards. Surviving lambs drink poorly and are very susceptible to cold stress. In some flocks it may be the principal mechanism causing perinatal mortality.

**CLINICAL PATHOLOGY**

Radiography of the skull is important to detect the presence and severity of fractures, which may have lacerated nervous tissue. CSF should be sampled from the cerebellomedullary cistern and examined for evidence of red blood cells. Extreme care must be taken to ensure that blood vessels are not punctured during the sampling procedure as this would confound the interpretation of the presence of red blood cells. The presence of heme pigments in the CSF suggests the presence of pre-existing hemorrhage; the presence of eosinophils or hypersegmented neutrophils suggests parasitic invasion.

**NECROPSY FINDINGS**

In most cases a gross hemorrhagic lesion will be evident but in concussion and nematodiasis the lesions may be detectable only on histological examination.

**DIFFERENTIAL DIAGNOSIS**

Unless a history of trauma is available diagnosis may be difficult.

**TREATMENT**

In those animals that recover consciousness within a few hours or earlier, the prognosis is favorable and little or no specific treatment may be necessary other than nursing care. When coma lasts for more than 3–6 hours the prognosis is unfavorable and slaughter for salvage or euthanasia is recommended. Treatment for edema of the brain as previously outlined may be indicated when treatment for valuable animals is requested by the owner. Animals that are still in a coma 6–12 hours following treatment are unlikely to improve and continued treatment is not warranted.

Focal diseases of the brain

**BRAIN ABSCESSES**

Abscesses of the brain occur most commonly in young farm animals under 1 year of age and rarely in older animals. Brain abscesses produce a variety of clinical signs depending on their location and size. Basically, the syndrome produced is one of a space-occupying lesion of the cranial cavity with some motor irritation signs. Localized or diffuse meningitis is also common, along with the effects of the abscess.

**ETIOLOGY**

Abscesses in the brain originate in a number of ways. Hematogenous infections are common, but direct spread from injury to the cranium or via the nasopharynx may also occur.

**Hematogenous spread**

The lesions may be single, but are often multiple, and are usually accompanied by meningitis. The infection usually originates elsewhere.

- *Actinobacillus mallei* from glanders lesions in lung
- *Streptococcus zooepidemicus* var. *equi* as a complication of strangles in horses
- *Corynebacterium pseudotuberculosis* in a goat causing an encapsulated abscess in the left cerebellar peduncle
- *Actinomyces bovis* and *Mycobacterium bovis* from visceral lesions in cattle
- *Fusobacterium necrophorum* from abscesses in the oropharynx of calves
- *Pseudomonas pseudomallei* in melioidosis in sheep
- *Staphylococcus aureus* in tick pyemia of lambs
- Systemic fungal infections such as cryptococcosis may include granulomatous lesions in brain.

**Local spread**

- Via peripheral nerves from oropharynx, the one specific disease is listeriosis in ruminants and New World camels
- Multifocal meningoencephalitis associated with lingual arteritis induced by barley spikelet clusters
- Space-occupying lesions of facial and vestibulocochlear nerves and geniculate ganglion secondary to otitis media in calves
- Abscess of rete mirabile of pituitary gland secondary to nasal septal infection after nose-ringing in cattle
- *Arcanobacterium (Actinomyces or Corynebacterium)* *pyogenes* is the most common isolate and several other species of bacteria that cause chronic suppurative lesions have been recovered. Similar abscesses, usually containing *A. pyogenes*, occur in the pituitary gland itself
- Extensions from local suppurative processes in cranial sinus after dehorning, from otitis media. The lesions are single, most commonly contain *A. pyogenes* and are accompanied by meningitis.

**PATHOGENESIS**

Infectious agents can invade the central nervous system by four routes:

- Retrograde infection via peripheral nerves
- Direct penetrating injuries
- Extension of adjacent supplicative lesions
- By way of the systemic circulation.

Single abscesses cause local pressure effects on nervous tissue and may produce some signs of irritation, including head pressing and mania, but the predominant effect is one of loss of function due to destruction of nerve cells. Multiple abscesses have much the same effect but whereas in single abscesses the signs usually make it possible to define the location of the lesion, multiple lesions present a confusing multiplicity of signs and variation in their severity from day to day, suggesting that damage has occurred at a number of widely distributed points and at different times.

The pituitary abscess syndrome has an uncertain pathogenesis. The pituitary gland is surrounded by a complex mesh of intertwined arteries and capillary beds known as the rete mirabile, which has been identified in cattle, sheep, goats, and pigs but not horses. This extensive capillary network surrounding the pituitary gland makes it susceptible to localization by bacteria that originate from other sources of infection. Nose-ringing of cattle may result in septic rhinitis, which could result in infection of the dural venous sinus system, which communicates with the subcutaneous veins of the nasal mucosa and cribiform plate. Cranial nerve deficits occur as a result of the extension of the abscess into the adjacent brainstem.

**CLINICAL FINDINGS**

General signs include mental depression, clumsiness, head pressing, and blindness, often preceded or interrupted by transient attacks of motor irritation including excitement, uncontrolled activity, and convulsions. A mild fever is usually present but the temperature may be normal in some cases.

The degree of blindness varies depending on the location of the abscess and the extent of adjacent edema and meningoencephalitis. The animal may be blind in one eye and have normal eyesight in the other eye or have normal eyesight in both eyes. Unequal pupils and abnormalities in the pupillary light reflex, both direct and consensual, are common. Uveitis, iris bombé, and a collection of fibrin in the anterior chamber of an eye may be present in some cases of multiple meningoencephalitis in cattle. Nystagmus is common when the lesion is near the vestibular nucleus; strabismus may also occur.

Localizing signs depend on the location of lesions and may include cerebellar ataxia, deviation of the head with circling and falling, hemiplegia or paralysis of individual or groups of cranial nerves often in a unilateral pattern. In the later stages there may be papilledema. In calves with lesions of the facial and vestibulocochlear nerves and geniculate ganglion, clinical signs may include drooping of the ears and lips, lifting of the nose, slight unilateral tilting of the head and uncontrolled saliva flow. Inability to swallow may follow and affected calves become dehydrated.

These localizing signs may be intermittent, especially in the early stages, and may develop slowly or acutely.

**Pituitary gland abscesses** are most common in ruminants, primarily cattle 2–5 years of age, but are relatively rare. The most common history includes anorexia, ataxia, depression, and drooling from the mouth with inability to chew and swallow. The most common clinical findings are depression, dysphagia, dropped jaw, blindness, and absence of pupillary light reflexes. Terminally, opisthotonos, nystagmus, ataxia, and recumbency are common. Characteristically, the animal stands with a base-wide stance, with its head and neck extended and its mouth not quite closed; there is difficulty in chewing and swallowing, and drooling of saliva. Affected animals are usually nonresponsive to external stimuli. Cranial nerve deficits are common, usually asymmetrical, multifocal and progressive. These include reduced tone of the jaw, facial paralysis, strabismus, and a head tilt. There may also be ptosis and prolapse of the tongue. Bradycardia has been recorded in about 50% of cases. Terminally there is opisthotonos, nystagmus, and loss of balance, followed by recumbency.

**CLINICAL PATHOLOGY**

**Cerebrospinal fluid**

Leukocytes, protein, and bacteria may be present in the CSF, but only when the abscess is not contained.

**Hematology**

In pituitary gland abscessation there may be hematological evidence of chronic infection including neutrophilia, hyperproteinemia, and increased fibrinogen.
although it is unlikely that a pituitary abscess itself is sufficiently large enough to induce these changes.

**Imaging**

Radiographic examination will not detect brain abscesses unless they are calcified or cause erosion of bone. Computed tomography has been used to diagnose a brain abscess in the horse.6

**Electroencephalography**

Electroencephalographic assessment of central blindness due to brain abscess in cattle has been reported.7

**NECROPSY FINDINGS**

The abscess or abscesses may be visible on gross examination and if superficial are usually accompanied by local meningitis.8 Large abscesses may penetrate to the ventricles and result in a diffuse ependymitis. Microabscesses may be visible only on histological examination. A general necropsy examination may reveal the primary lesion.

**DIFFERENTIAL DIAGNOSIS**

Brain abscess is manifested by signs of involuntary movements and loss of function, which can occur in many other diseases of the brain, especially when local lesions develop slowly. This occurs more frequently with tumors and parasitic cysts but may occur in encephalitis. The characteristics clinical findings are those of a focal or multifocal lesion of the brain, which include:

- Localizing signs of hemiparesis and ataxia
- Postural reaction defect
- Vestibular signs, including head tilt and positional nystagmus
- Cranial nerve deficits.

There may be evidence of the existence of a suppurative lesion in another organ, and a high cell count and detectable infection in the CSF to support the diagnosis of abscess. Fever may or may not be present. The only specific disease in which abscess occurs is listeriosis, in which the lesions are largely confined to the medulla oblongata and the characteristic signs include circling and unilaterial facial paralysis. Occasional cases may be associated with fungal infections, including cryptococcosis. Toxoplasmosis is an uncommon cause of granulomatous lesions in the brain of most species.

Many cases of brain abscesses are similar to otitis media but there is, in the latter, rotation of the head, a commonly associated facial paralysis and an absence of signs of cerebral depression.

- The pituitary gland syndrome in cattle must be differentiated from listeriosis, polioencephalomalacia, lead poisoning, other brain abscesses and thombomeningoencephalitis. In sheep and goats, Paralaeophosphorlyus tenuis infection and caprine arthritis encephalomyelitis syndrome may resemble the pituitary gland abscess syndrome.

**TREATMENT**

Parenteral treatment with antimicrobials is indicated but the results are generally unsatisfactory because of the inaccessible of the lesion, with the clear exception being listeriosis. Treatment of pituitary gland abscess is not recommended, and an antemortem diagnosis is rarely obtained.

**REFERENCES**

**OTTIS MEDIA/INTERNA**

Infection of the middle ear (otitis media) occurs in young animals of all species but especially dairy calves and pigs, to a lesser extent feedlot cattle and lambs, and rarely foals. The infection may gain entrance from the external ear (e.g. caused by ear mite infestation) or hematogenously, but the spread is chiefly an ascending infection of the eustachian tubes in a young animal from a respiratory tract infection. Extension of infection into the inner ear leads to otitis interna.

**Pigs**

Otitis media was present in 68% of 237 pigs that were slaughtered because of illness.1 It is suggested that otitis media in pigs develops first as an acute inflammation in the auditory tube and then extends to other parts of the ear and brain. When abscesses form at the ventrum of the brainstem, the vestibulocochlear nerve is usually involved in the lesion.2 Infection in the ear may extend into the brain by following the auditory nerve. Perilymph filling the scala vestibuli and scala tympani is also a possible tract for the extension of the infection because there is a communication between the perilymph-filled spaces of the bony labyrinth and the subarachnoid space.

Calves and lambs

The peak of occurrence in calves and lambs is 1-4 weeks of age. The highest prevalence is in sucking dairy calves and weaned cattle and sheep in feedlots, where the disease is probably secondary to respiratory tract infection. Outbreaks of otitis media/interna have occurred in beef calves from 6-10 weeks of age on pasture with their dams; mixed cultures of Escherichia coli, Pseudomonas spp., and Acinetobacter spp. were isolated.3 Otitis media/interna in sucking dairy calves can also occur in outbreaks, and Mycoplasma bovis is frequently isolated from the middle and inner ears of affected calves.4

The onset of clinical signs commonly includes dullness, fever, inappetence, tachypnea, and a purulent discharge from the affected ear accompanied by rotation of the head (in otitis interna) and drooping of the ear a few days later due to involvement of the facial nerve in the inflammation.5 Deep palpation at the base of the ears may elicit a pain response.3

Rotation of the head, with the affected side down and facial paralysis may occur on the same side, and walking in circles with a tendency to fall to the affected side is common. In most cases the animals are normal in other respects, although depression and inappetence can occur in advanced cases.

**Horses**

Otitis media/interna occurs in horses4 and two clinical syndromes have been described.

The first syndrome is primary otitis media characterized by abnormal behavior, including head tossing, head shaking, and ear rubbing.4 Violent, uncontrollable behavior includes throwing themselves on the ground, rolling, and thrashing. This may progress to involve the bony structures of the temporal and proximal stylohyoid bones, resulting in a degenerative arthritis and eventual fusion of the temporohyoid bone.

The second syndrome is characterized by an acute onset of neurologic deficits. Commonly, there is vestibulocochlear nerve and often facial nerve dysfunction characterized by head tilt to the side of the lesion, nystagmus with the slow component to the affected side and weakness of the extensor muscles on the affected side resulting in an ataxia or reluctance or refusal to stand. Horses that can stand often will lean on walls for support of the affected side.

Definitive diagnosis is dependent on either a positive tympanocentesis or, in the majority of cases, bony proliferation of the temporal bone and proximal part of the stylohyoid bone, or lysis of the tympanic bulla, as determined by radiography4 or computed tomography.5
the auditory tube diverticula in horses with otitis media/interna. In some cases, the tympanic membrane is ruptured, which can be seen using an otoscope. 

Tympanocentesis is done under general anesthesia in horses or sedation in ruminants by directing a 15 cm needle through the tympanic membrane visualized with the aid of an otoscope. The technique is somewhat difficult because of the long and angled external auditory canal. Sterile 0.9% NaCl (0.5–1 mL) is injected into the tympanic cavity and then, after a few seconds, withdrawn. A positive tap consists of withdrawal of a cloudy or yellow fluid, which on analysis may contain evidence of pus and can be sampled for culture and antimicrobial susceptibility.

**DIFFERENTIAL DIAGNOSIS**

The disease needs to be differentiated from otitis externa, in which the head may be carried in a rotated position, but usually intermittently, and this is accompanied by head shaking and the presence of exudate and an offensive smell in the ear canal, and from cerebral injury or abscess, and similar lesions of the upper cervical cord. All of these are characterized by deviation of the head, not rotation. At necropsy the tympanic bulla contains pus, and a variety of organisms, such as staphylococci, streptococci, Pasteurella haemolytica, and Neisseria catarrhalis, may be isolated.

**TREATMENT**

Treatment consists of broad-spectrum antimicrobials for 4 weeks, and anti-inflammatory agents. The prognosis with treatment for fluoroquinolones is very good in calves, although a 50% mortality rate has been reported in calves that were not treated with other antimicrobial agents. The use of lincomycin at 6.5 mg/kg BW combined with spectinomycin at 10 mg/kg BW intravenously twice daily for 5 days has been reported to be successful for the treatment of otitis media in beef calves. Anecdotal reports exist in cattle of using a knitting needle to rupture the tympanic membrane, with rapid resolution of the head tilt because of the decreased pressure in the middle ear. Bilateral tympanic bulla osteotomy has been performed in an affected calf, resulting in a rapid resolution of the head tilt.

**DISEASES OF THE NERVOUS SYSTEM**

Primary tumors of the central nervous system are extremely rare in farm animals. They produce a syndrome indicative of a general increase in intracranial pressure and local destruction of nervous tissue. Tumors of the peripheral nervous system are more common.

**ETIOLOGY**

The reader is referred to the review literature for a summary of available references on the tumors of the central nervous system of farm animals, which include:

- Meningeal tumors in cattle
- Equine papillary ependymoma.

**PATHOGENESIS**

The development of the disease parallels that of any space-occupying lesion, with the concurrent appearance of signs of increased intracranial pressure and local tissue destruction. Many lesions found incidentally at necropsy may not have had any related clinical findings.

**CLINICAL FINDINGS**

The clinical findings are similar to those caused by a slowly developing abscess and localizing signs depend on the location, size, and speed of development of the tumor. Clinical signs are usually representative of increased intracranial pressure, including opisthotonos, convolutional disturbances, and head pressing. Common localizing signs include circling, deviation of the head, and disturbance of balance. Lesions close to the pituitary gland may cause diabetes insipidus and Cushings syndrome. A 17-year-old horse with an ependymoma had an 18-month history of slowly progressive ataxia culminating in a sudden loss of ability to control the pelvic limbs, with dog-sitting, spinning, and falling.

**CLINICAL PATHOLOGY**

There are no positive findings in clinicopathological examination which aid in diagnosis.

**NECROPSY FINDINGS**

The brain should be carefully sectioned after fixation if the tumor is deep-seated.

**TREATMENT**

There is no treatment.

**REFERENCES**

**CENTRAL-NERVOUS-SYSTEM-ASSOCIATED TUMORS**

The pituitary gland (hypophysis) consists of the adenohypophysis (pars distalis, intermediate, and tuberalis) and the neurohypophysis (pars nervosa). Tumors of the pituitary gland occur in the horse.

Cushing’s syndrome in horses almost invariably originates from an adenoma of the pars intermedia of the pituitary gland. Initially, these animals exhibit only one remarkable sign, namely, hirsutism. Horses with Cushing’s disease only do not manifest polyuria and polydipsia. Major sequelae of an adenoma of the pars intermedia of the pituitary gland are type 2 diabetes mellitus and laminitis. Diagnosis of an adenoma of the pars intermedia of the pituitary gland in the horse mainly depends on dynamic endocrinological function tests. The sensitivity of the adrenocorticotropic (ACTH) test is about 80%.

**REFERENCES**

**METASTATIC TUMORS OF THE CENTRAL NERVOUS SYSTEM**

Many primary tumors of non-nervous tissue have the potential for metastasis to the central nervous system. Ocular squamous cell carcinoma of cattle may invade the cranial nerves through the cribiform plate.

Lymphomas of cattle may metastasize to the central nervous system with either a multicentric distribution or occasionally as the only lesion. Many primary tumors of bovine lymphoma occur as an epidural mass in the vertebral canal. Intracranial lymphoma usually involves the leptomeninges or the choroid plexus. Clinical signs are related to the progressive compression of the nervous system in the cranial cavity.
nervous tissue at the site of the mass. Lymphoma in the horse has occurred in the epidural space with spinal cord compression.

**CENTRAL-NERVOUS-SYSTEM-ASSOCIATED MASSES**

Cholesterinic granulomas, also known as cholesteatomas may occur in up to 20% of older horses without any clinical effects. However, they can be associated with significant neurological disease. Affected horses are commonly obese. Cholesterinic granulomas occur in the choroid plexus of the fourth ventricle or in the lateral ventricles and mimic cerebrocortical disease. It has been suggested that cholesterol granulomas result from chronic hemorrhage into the plexus stroma but the underlying pathogenesis is unknown.

Brownish nodular thickening of the plexuses with glistening white crystals is a common incidental finding in mature and aged horses. Occasionally, deposits in the plexuses of the lateral ventricles are massive and fill the ventricular space and cause secondary hydrocephalus due to the build up of CSF behind the mass. CSF may be xanthochromic with an elevated total protein.

**Clinical findings** include episodes of abnormal behavior such as depression and bolting uncontrollably, running into fences and walls. Some horses exhibit profound depression, somnolence, and reluctance to move. Seizures have also been reported.

Other clinical findings reported include decreased performance, aggression, head tilt, incoordination, intermittent convulsions, hindlimb ataxia progressing to recumbency, intermittent circling in one direction, and spontaneous twitches along the back and flank. There are often serious changes in temperament, with previously placid animals becoming violent and aggressive. In others there are outbursts of frenzied activity followed by coma. The horse may be normal between attacks and these may be precipitated by moving the head rapidly.

These signs are referable to cerebrocortical disease and the differential diagnosis of cholesteric granulomas must include diffuse cerebral encephalopathy due to abscess, tumor, toxicosis, metabolic disease, encephalomyelitis, trauma, and hydrocephalus. At necropsy, large cholesterol granulomas are present in the choroid plexus.

**REFERENCES**

**COENUROSIS (GID, STURDY)**

Coenurosis is the disease caused by invasion of the brain and spinal cord by the intermediate stage of *Taenia multiceps*. The syndrome produced is one of localized, space-occupying lesions of the central nervous system. In most countries the disease is much less common than it used to be and relatively few losses occur.

**ETIOLOGY**

The disease is associated with *Coenurus cerebralis*, the intermediate stage of the tapeworm *T. multiceps*, which inhabits the intestine of dogs and wild Canidae. The embryos, which hatch from eggs ingested in feed contaminated by the feces of infested dogs, hatch in the intestine and pass into the bloodstream. Only those embryos that lodge in the brain or spinal cord survive and continue to grow to the coenurid stage. *C. cerebralis* can mature in the brain and spinal cords of sheep, goats, cattle, horses, and wild ruminants, and occasionally humans, but clinical coenurosis is primarily a disease of sheep and occasionally cattle. Infection in newborn calves, acquired prenatally, has occasionally been observed.

**PATHOGENESIS**

The early stages of migration through nervous tissue usually pass unnoticed, but in heavy infections an encephalitis may be produced. Most signs are caused by the mature coenurus, which may take 6–8 months to develop to its full size of about 5 cm. The cyst-like coenurus develops gradually and causes pressure on nervous tissue, resulting in its irritation and eventual destruction. It may cause sufficient pressure to rarefy and soften cranial bones.

**CLINICAL FINDINGS**

In acute outbreaks due to migration of larval stages, sheep show varying degrees of blindness, ataxia, muscle tremors, nystagmus, excitability, and collapse. Sheep affected with the mature coenurus show an acute onset of irritation phenomena including a wild expression, salivation, frenzied running and convulsions. Deviation of the eyes and head may also occur. Some animals may die in this stage but the greater proportion go on to the second stage of loss of function phenomena, the only stage in most affected animals. The most obvious sign is slowly developing partial or complete blindness in one eye. Dullness, clumsiness, head-pressing, ataxia, inconstable mastication and periodic epileptiform convulsions are the usual signs. Papilledema may be present. Localizing signs comprise chiefly deviation of the head and circling; there is rotation of the head with the blind eye down, and deviation of the head with circling in the direction of the blind eye.

In young animals local softening of the cranium may occur over a superficial cyst and rupture of the cyst to the exterior may follow, with final recovery. When the spinal cord is involved there is a gradual development of paresis and eventually inability to rise. Death usually occurs after a long course of several months.

**CLINICAL PATHOLOGY**

Clinicopathological examinations are not generally used in diagnosis in animals and serological tests are not sufficiently specific to be of value. Radiological examinations are helpful in defining the location of the cyst, especially if there is a prospect of surgical intervention.

**DIFFERENTIAL DIAGNOSIS**

The condition needs to be differentiated from other local space-occupying lesions of the cranial cavity and spinal cord, including abscess, tumor, and hemorrhage. In the early stages the disease may be confused with encephalitis because of the signs of brain irritation. Clinically there is little difference between them and, while clinical signs and local knowledge may lead to a presumptive diagnosis, demonstration of the metacestode is essential.

**TREATMENT AND CONTROL**

Surgical drainage of the cyst may make it possible to fatten the animal for slaughter, and surgical removal with complete recovery is possible in a majority of cases. The life cycle can be broken most satisfactorily by control of mature tape worm infestation in dogs. Periodic treatment of all farm dogs with a tenicide is essential for control of this and other more pathogenic tapeworms. Carcasses of livestock infested with the intermediate stages should not be available to dogs.

**DISEASES OF THE MENINGES**

**MENINGITIS**

Inflammation of the meninges occurs most commonly as a complication of
a pre-existing disease. Meningitis is usually associated with a bacterial infection and is manifested clinically by fever, cutaneous hyperesthesia, and rigidity of muscles. Although meningitis may affect the spinal cord or brain specifically, it commonly affects both and is dealt with here as a single entity. Meningoencephalitis is common in neonatal farm animals. Primary bacterial meningitis is extremely rare in adult farm animals, with the exception of listeriosis and Histophilus somni (formerly *Haemophilus somnis*) infection, although the latter is more a vasculitis than a primary meningitis. The possibility of immunodeficiency should be considered in adult horses with bacterial meningitis.1

**ETIOLOGY**

Most significant meningitides are bacterial, although most viral encephalitides have some meningitic component.

- **Cattle**
  - Viral diseases – bovine malignant catarrh, sporadic bovine encephalomyelitis
  - Bacterial diseases – listeriosis, *H. somni*, chronic lesions elsewhere in the body possibly associated with meningitis in adult animals;2 rarely tuberculosis.

- **Horses**
  - Strangles, *Pasteurella haemolytica* (also donkeys and mules), *Streptococcus suis*, *Streptococcus equi*, *Actinomyces* spp.

- **Sheep**
  - *Melioidosis, S. aureus* (tick pyemia) in newborn lambs
  - *Pasteurella multocida* in lambs
  - *Moraxella (Pasteurella) haemolytica* in lambs.

- **Pigs**
  - Glasser's disease, erysipelas, salmonellosis; *S. suis* type 2 in weaned and feeder pigs.

Young animals generally

*Streptococcal* and *coliform* septicemias are probably the commonest causes of meningitis in neonatal farm animals. The infection may originate from an omphalophlebitis, bacteraemia,3 or bacterial translocation across the gastrointestinal tract in neonates less than 24 h of age or with enteritis. Septicemia occurs in all species, especially calves, and may be accompanied by polysynovitis, endocarditis, and hypopyon. The causative bacteria are usually a mixed flora,4

Hematogenous infection occurs from other sites also. In neonatal animals, some of the common infections are:

- **Calf** – *E. coli*. The disease occurs most commonly in calves under several days of age and can occur in less than 24 hours after birth. Failure of transfer of colostral immunoglobulins is a common contributing factor

- **Piglet** – *Streptococcus zooepidemicus*, *S. suis* type 1

- **Lamb** – *S. zooepidemicus*.

**PATHOGENESIS**

Inflammation of the meninges causes local swelling and interference with blood supply to the brain and spinal cord but as a rule penetration of the inflammation along blood vessels and into nervous tissue is of minor importance and cause only superficial encephalitis. Failure to treat meningitis associated with pyogenic bacteria often permits the development of a fatal choroiditis, with exudation into CSF, and ependymitis. There is also inflammation around the nerve trunks as they pass across the subarachnoid space. The signs produced by meningitis are thus a combination of those resulting from irritation of both central and peripheral nervous systems. In spinal meningitis there is muscular spasm with rigidity of the limbs and neck, arching of the back and hyperesthesia with pain on light touching of the skin. When the cerebral meninges are affected, irritation signs, including muscle tremor and convulsions, are the common manifestations. Since meningitis is usually bacterial in origin, fever and toxemia can be expected if the lesion is sufficiently extensive.

Defects of drainage of CSF occur in both acute and chronic inflammation of the meninges and produce signs of increased intracranial pressure. The signs are general although the accumulation of fluid may be localized to particular sites such as the lateral ventricles.

**CLINICAL FINDINGS**

Acute meningitis usually develops suddenly and is accompanied by fever and toxemia in addition to nervous signs. Vomiting is common in the early stages in pigs. There is trismus, opisthotonos, and rigidity of the neck and back. Motor irritation signs include tonic spasms of the muscles of the neck causing retraction of the head, muscle tremor and paddling movements. Cutaneous hyperesthesia is present in varying degrees, even light touching of the skin causing severe pain in some cases. There may be disturbance of consciousness manifested by excitement or mania in the early stages, followed by drowsiness and eventual coma.

Blindness is common in cerebral meningitis but not a constant clinical finding. In young animals, opthalmitis with hypopyon may occur, which supports the diagnosis of meningitis. The pupillary light reflex is usually much slower than normal. Examination of the fundus of the eyes may reveal evidence of optic disk edema, congestion of the retinal vessels and exudation.

In uncomplicated meningitis the respiration is usually slow and deep, and often phasic in the form of Cheyne-Stokes breathing (a breathing pattern characterized by a period of apnea followed by a gradual increase in the depth and rate of respiration) or Biot's breathing (a breathing pattern characterized by unpredictable irregularity). Terminally there is quadriplegia and clonic convulsions.

The major clinical finding of meningoencephalitis in calves under 2 weeks of age was depression which progressed rapidly to stupor but the mental state changed to hyperegesia, opisthotonos and seizures in unresponsive terminal cases.5 Meningoencephalitis should be considered in calves that have been treated for the effects of diarrhea with fluid therapy but fail to respond and remain depressed.

In a series of 32 cases of meningitis in neonatal calves, the mean age at admission was 6 days (range, 11 hours–30 days). The major clinical findings were lethargy (32/32), recumbency (32/32), anorexia and loss of the suck reflex (26/32), and stupor and coma (21/32).6 The frequency of other clinical findings were as follows: opisthotonos (9/32), convulsions (7/32), tremors (6/32), and hyperesthesia (6/32). The case fatality rate was 100%.

Although meningitis in farm animals is usually diffuse, affecting particularly the brainstem and upper cervical cord, it may be quite localized and produce localizing signs, including involvement of the cranial or spinal nerves. Localized muscle tremor, hyperesthesia and rigidity may result. Muscles in the affected area are firm and board-like on palpation. Anesthesia and paralysis usually develop caudal to the meningitic area. Spread of the inflammation along the cord is usual. Reference should be made to the specific diseases cited under Etiology for a more complete description of their clinical manifestations.

In newborn calves, undifferentiated diarrhea, septic arthritis, omphalophlebitis and uveitis are frequent concurrent clinical findings. Bacterial meningitis has been reproduced experimentally in calves, resulting in typical clinical signs consisting of convulsions, depression, circling and falling to one side, ataxia, propulsive walking, loss of saliva, tremors, recumbency, lethargy, and nyctagmus.7
CLINICAL PATHOLOGY
Cerebrospinal fluid
CSF collected from the lumbosacral space or cisterna magna in meninges contains elevated protein concentrations, has a high cell count and usually contains bacteria.\(^4,7\) The collection of CSF from the lumbosacral space of calves has been described under the section on Special examination of the nervous system.\(^7\) Culture and determination of drug sensitivity of the bacteria is advisable because of the low concentrations of antimicrobial agents achieved in CSF. In a series of meningitis in neonatal calves, the CSF revealed pleocytosis (mean 4000 leukocytes/μL; range, 130-23 270 leukocytes/μL), xanthochromia, turbidity and a high total protein concentration.\(^3\)

Hematology
The hemogram usually reveals a marked leukocytosis, reflecting the severity of the systemic illness secondary to sepsis.

NECROPSY FINDINGS
Hyperemia, the presence of hemorrhages, and thickening and opacity of the meninges, especially over the base of the brain, are the usual macroscopic findings. The CSF is often turbid and may contain fibrin. A local superficial encephalitis is commonly present. Additional morbid changes are described under the specific diseases and are often of importance in differential diagnosis. In neonatal calves with meningitis, lesions of septicaemia are commonly present at necropsy and \(E.\ coli\) is the most commonly isolated organism.

DIFFERENTIAL DIAGNOSIS
Hyperesthesia, severe depression, muscle rigidity, and blindness are the common clinical findings in cerebral meningitis but it is often difficult to differentiate meningitis from encephalitis and acute cerebral edema. Examination of the CSF is the only means of confirming the diagnosis before death. Analysis of CSF is very useful in the differential diagnosis of diseases of the nervous system of ruminants.\(^7,8\) Details are presented under Examination of CSF in the section on Special examination of the nervous system. Subacute or chronic meningitis is difficult to recognize clinically. The clinical findings may be restricted to recumbency, apathy, anorexia, slight incoordination if forced to walk and some impairment of the eyesight. Spinal cord compression is usually more insidious in onset and is seldom accompanied by fever; hyperesthesia is less marked or absent and there is flaccidity rather than spasticity.

TREATMENT
The infection is usually bacterial, and parenteral treatment with antimicrobial agents is necessary. Large doses daily for several days are required. The levels of antimicrobial agents that are achieved in the meninges and CSF following parenteral administration to farm animals are not known. Presumably, the blood–brain and blood–CSF barriers are not intact in meningitis and minimum inhibitory concentrations of some drugs may be achieved.

Antimicrobial agents
The injection of antimicrobial agents into the cerebrospinal fluid cistern or into the lumbosacral space is not recommended. If parenteral treatment with the antimicrobial of choice, determined by a susceptibility test, does not result in a beneficial response in 3–5 days the prognosis is unfavorable.

The choice of antimicrobial agent will depend on the suspected cause of the meningitis. The common antibiotics, such as penicillin and oxytetracycline, are effective for the treatment of meningococcal meningitis in cattle due to \(H. somni\) when treatment is begun early. Neonatal streptococcal infections also respond beneficially to penicillin when treated early before irreparable injury has occurred.

The response to therapy will depend on the causative pathogen and the severity of the inflammation present. Some cases of meningitis, such as that in swine associated with \(S.\ suis\) type 2, commonly do not respond to treatment when clinical signs are obvious. Conversely, the meningococcal meningitis in cattle associated with \(H. somni\) will respond dramatically if treatment is begun as soon as clinical signs are apparent. The prognosis in meningitis associated with infection with \(E.\ coli\) is unfavorable. In a series of 32 cases admitted to a veterinary teaching hospital, even after intensive therapy the case fatality rate was 100%.\(^3\)

Cephalosporins
Based on recent experiences in human medicine, the most promising antimicrobials for the treatment of meningitis in farm animals, particularly the neonates, may be the new third-generation cephalosporins, which resist hydrolysis by beta-lactamases, have enhanced penetration into the CSF and are bactericidal at very low concentrations.\(^5\) Clinical experience with these agents in the treatment of neonatal meningitis has been very encouraging. The aminoglycosides are also indicated in the treatment of meningitis in newborn animals.\(^5\) Moxalactam and cefotaxime are used widely for the treatment of Gram-negative bacillary meningitis in human and cefazidime is equally effective.\(^4\) Trimethoprim-sulfonamide combinations, with or without gentamicin, which is synergistic with the former, are also recommended. The principles of the pharmacotherapeutics of bacterial meningitis in farm animals have been reviewed.\(^4\)

REVIEW LITERATURE

REFERENCES

Toxic and metabolic encephalomyelopathies
A very large number of poisons, especially poisonous plants and farm chemicals, and some metabolic defects cause abnormalities of function of the nervous system. Those plants that cause degenerative nervous system disease are listed under encephalomalcia; those that cause no detectable degenerative change in tissue are listed here.

A partial list of toxins and metabolic errors or imbalances that can cause nervous system dysfunction are as follows.

Abnormalities of consciousness and behavior
- Hypoglycemia and ketonemia of pregnancy toxemia (with degenerative lesions in some) and acetoneemia
- Depression due to strong ion (metabolic) acidosis associated with diarrhea and dehydration, particularly in neonatal animals
- Hypomagnesemia of lactation tetany
- Hyper-D-lactatemia in neonatal calves with diarrhea and adult ruminants with grain overload
- High blood levels of ammonia in hepatic insufficiency
- Unspecified toxic substances in uremic animals
- Exogenous toxins, including carbon tetrachloride, hexachloroethane, and trichloroethylene
- Plants causing anemic and histotoxic hypoxia, especially plants causing cyanide or nitrite poisoning
- Poison plants, including \(Helichrysum\) spp., tansy mustard, male fern, kikuyu grass (or a fungus, \(Myrothecium\) sp. on the grass).
Abnormality characterized by tremor and ataxia
- Weeds, including Conium spp. (hemlock), Eupatorium spp. (snakeroot), Sarcostemma spp., Euphorbia spp. and Karwinskia spp.
- Bacterial toxins in shaker foal syndrome (probably)
- Fungal toxins, e.g. Acremonium lolii, the fungus of ryegrass staggers.

Convulsions
- Metabolic deficits, including hypoglycemia (piglets, ewes with pregnancy toxemia), hypomagnesemia (of whole milk tetany of calves, lactation tetany, cows and mares)
- Nutritional deficiencies of vitamin A (brain compression in calves and pigs), pyridoxine (experimentally in calves)
- Inorganic poisons, including lead (calves), mercury (calves), farm chemicals such as organic arsenicals (pigs), organophosphates, chlorinated hydrocarbons, strychnine, urea, metaldehyde
- Bacterial toxins, including Clostridium tetani, Clostridium perfringens type D
- Fungal toxins, e.g. Claviceps purpurea
- Grasses, including Wimmera ryegrass (Lolium rigidum) or the nematode on it, Echinopogon ovatus
- Pasture legumes – lupines
- Weeds – Oenothera spp. (hemlock water dropwort), Indigophora spp. (in horses), Cicuta spp. (water hemlock), Albizia tayangynicis, Sarcostemma spp. and Euphorbia spp.
- Trees – laburnum, oleander, supplejack (Ventilago spp.).

Ataxia apparently due to proprioceptive defect
- Grasses – Phalaris tuberosa (aquatica) (and other Phalaris spp.), Lolium rigidum, Echinopogon ovatus
- Trees – Kalmia spp., Erythrophleum spp., Eupatorium rugosum
- Ferns – Xanthorrhoea spp., Zamia spp.

Involuntary spastic contraction of large muscle masses
This includes, for example, Australian stringhalt caused by Arctotheca calendula (flatweed).

Tremor, incoordination, and convulsions
There is an additional long list of plants that cause diarrhea and nervous signs, especially ataxia, together, but whether the latter are due to the former or caused by neurotoxins is not identified.

The nervous signs include tremor, incoordination, and convulsions.

Paresis or paralysis
Many of the toxic substances and metabolic defects listed above cause paresis when their influence is mild and paralysis when it is severe. Some of the items appear in both lists. Because an agent appears in one list and not the other is not meant to suggest that it does not cause the other effect. It is more likely that it occurs in circumstances that are almost always conducive to the development of a mild syndrome (or a severe one, as the case may be).

Disturbance of function at neuromuscular junctions e.g.: hypocalcemia, hypomagnesemia, hypokalemia (as in downer cows), tetanus, botulism and hypoglycemia of pregnancy toxemia in cows and ewes, and tick paralysis. Hypophosphatemia has not been demonstrated to be a definitive cause of weakness in cattle.

Nutritional deficiency, but including only experimentally induced deficiency of nicotinic and pantothenic acids: biotin and choline, cause posterior paresis and paralysis in pigs and calves

Toxic diseases of the nervous system, including disease associated with many chemicals used in agriculture, e.g.: nicotine sulfate, rotenone, 2,4-D and 2,4,5-T, organophosphates, carbamates, chlorinated hydrocarbons, propylene glycol, metaldehyde, levamisole, tolune, carbon tetrachloride, strychnine, and nicotine sulfate.

Psychoses or neuroses
Psychoses or neuroses are extremely rare in farm animals, although the vices of crib-biting and weaving in horses could be included in this category.

Crib-biting and windsucking
Crib-biting is an acquired habit in which the horse grasps an object, usually the feed box or any solid projection, with the incisor teeth, then arches the neck and, by depressing the tongue and elevating the larynx, pulls upwards and backwards and swallows air, emitting a loud grunt at the same time. This results in erosion of the incisor teeth, intermittent bouts of colic and flatulence. Crib-biting must be distinguished from chewing wood due to boredom and from pica due to a mineral deficiency. Some horses perform similarly but do not actually seize the object with their teeth; they just rest their teeth or their chin on it.

Wind sucking is the vice in which the horse flexes and arches the neck and swallows air and grunts but there is no grasping of objects.

Grasping is the seizing of an object with the teeth but without swallowing of air.

Kicking, pawing, circling, weaving
Persistent kicking of the stall, in the absence of pruritic lesions of the lower limbs, continuous circling of a stall, pawing of the floor with a forefoot and weaving, standing at the window looking out while rocking from one foot to the other and swinging the head and neck to the same side, are all neurotic vices caused by boredom in active horses. The extreme case is the animal that bites itself and causes cutaneous and subcutaneous mutilation.

Farrowing hysteria
Hystera in sows at farrowing is a common occurrence. This syndrome occurs most commonly in gilts. Affected animals are hyperactive and restless and they attack and savage their piglets as they approach the head during the initial teat sucking activity after birth. Serious and often fatal injuries result. Cannibalism is not a feature.

When the syndrome occurs, the remaining piglets and freshly born piglets should be removed from the sow and placed in a warm environment until parturition is finished. The sow should then be tested to see if she will accept the piglets. If not, ataractic or neuroleptic drugs should be administered to allow initial sucking, after which the sow will usually continue to accept the piglets.

Azaperone (2 mg/kg BW) is usually satisfactory and pentobarbital sodium administered intravenously until the pedal reflex is lost has been recommended. Promazine derivatives are effective but subsequent incoordination may result in a higher crushing loss of piglets. The piglets’ teeth should be clipped.

Affected gilts should be culled subsequently as the syndrome may recur at subsequent farrowing. Where possible, gilts should be placed in their farrowing accommodation 4–6 days before parturition and the farrowing environment should be kept quiet at the time of parturition.

Tail-biting, ear-chewing, snout-rubbing
The incidence of cannibalism has increased with intensification of pig rearing.
and it is now a significant problem in many pig-rearing enterprises. Tail-biting is the most common and occurs in groups of pigs, especially males, from weaning to market age. Ear-chewing is less common and is generally restricted to pigs in the immediate postweaning and early growing period, although both syndromes may occur concurrently. The incidence of ear-chewing has increased with the practice of docking piglet tails at birth.

Tail-biting usually begins with one or two pigs sucking or chewing the tails of pen mates. Initially the practice causes no resentment but as the tail becomes raw and eroded, pain is shown. Rarely, if the offending agonists are removed at this stage, the problem will not progress. Generally the raw eroded tail becomes attractive to other individuals within the group and the vice spreads within the group to involve the majority of pigs. Most of the tail may eventually be removed, leaving a raw bleeding stump.

Productivity is affected by severe lesions and sequelae such as spinal abscission with paralysis and abscession or pyemia with partial or total carcass condemnation are not uncommon.

Ear-biting occurs in similar fashion. The lesions are usually bilateral and most commonly involve the ventral part of the ear. Lesions from bite wounds may also occur on the flanks of pigs. There is frequently an association with mange infestation with both of these vices.

A syndrome of snout-rubbing to produce eroded necrotic areas on the flanks of pigs has been described. Affected pigs were invariably colored, although both white and colored pigs acted as agonists.

The causes of these forms of cannibalism in pigs are poorly understood but they are undoubtedly related to an inadequate total environment. Affected groups are usually more restless and have heightened activity. Factors such as high population density, both in terms of high pen density and large group size, limited food and competition for food, low protein and inadequate nutrition, boredom and inadequate environment in terms of temperature, draft and ventilation have been incriminated in precipitating the onset of these vices.

When a problem is encountered each of these factors should be examined and corrected or changed if necessary. Prevention is through the same measures. Chains or tires are frequently hung for displacement activity but are not particularly effective.

The problem may recur despite all attempts at prevention. Also for economic reasons it is not always possible to implement the radical changes in housing and management that may be necessary to avoid the occurrence of these vices. Because of this, the practice of tipping or docking the piglets' tails at birth has become common as a method of circumventing the major manifestation of cannibalism.

Epilepsy
Seizures occur most frequently in conjunction with other signs of brain disease. The syndrome of inherited, recurrent seizures, which continues through life with no underlying morphological disease process, is true epilepsy, which is extremely rare in farm animals. Familial epilepsy has been recorded in Brown Swiss cattle and is described under that heading in Chapter 12.

Residual lesions after encephalitis may cause symptomatic epileptiform seizures but there are usually other localizing signs. A generalized seizure is manifested by an initial period of alertness, the counterpart of the aura in human seizures, followed by falling into a state of tetany, which gives way after a few seconds to a clonic convulsion with paddling, opisthotonos and champing of the jaws. The clonic convulsions may last for some minutes and are followed by a period of relaxation. The animal is unconscious throughout the seizure, but appears normal shortly afterwards.

Some seizures may be preceded by a local motor phenomenon such as twitching or tremor of one limb or of the face. The convulsion may spread from this initial area to the rest of the body. This form is referred to as Jacksonian epilepsy and the local sign may indicate the whereabouts of the local lesion or point of excitation. Such signs are recorded very rarely in dogs and not at all in farm animals. The seizures are recurrent and the animal is normal in the intervening periods.

Diseases of the spinal cord

TRAUMATIC INJURY
Sudden severe trauma to the spinal cord causes a syndrome of immediate, complete, flaccid paralysis caudal to the injury because of spinal shock. This is so brief in animals as to be hardly recognizable clinically. Spinal shock is soon followed by flaccid paralysis in the area supplied by the injured segment and spastic paralysis caudal to it.

ETIOLOGY
Trauma is the most common cause of monoplegia in large animals. There are varying degrees of loss of sensation, paresis, paralysis, and atrophy of muscle.

Physical trauma
- Animals falling off vehicles, through barn floors
- Osteoprotic or osteodystrophic animals, especially aged brood mares and sows, spontaneously while jumping or leaning on fences
- Spondylosis and fracture of thoracolumbar vertebrae in old bulls in insemination centers
- Cervical vertebral fractures account for a large percentage of spinal cord injuries in horses
- Trauma due to excessive mobility of upper cervical vertebrae may contribute to the spinal cord lesion in wobblers in horses
- Dislocations of the atlanto-occipital joint are being reported increasingly
- Stenosis of the cervical vertebral canal at C2-C4 in young rams, probably as a result of head-butting
- Fracture of T1 vertebra in calves turning violently in an alleyway wide enough to admit cows
- Vertebral fractures in 7-10-month-old calves escaping under the head gate of chute and forcefully hitting their backs (just cranial to the tuber coxae) on the bottom rail of the gate
- Vertebral fractures in neonatal calves associated with forced extraction during dystocia
- Lightning strike may cause tissue destruction within the vertebral canal.

Parasitic invasion
- Cerebrospinal nematodiasis, e.g. *Paraechinophthorongulatus tenuis*, *Setaria* spp. in goats and sheep, *Stephanurus dentatus* in pigs, *P. tenuis* in moose, causing moose sickness
- *Toxocara canis* experimentally in pigs
- *Strongylus vulgaris* in horses and donkeys
- *Hypoderma bovis* larvae in cattle.

Local ischemia of the spinal cord
- Obstruction to blood flow to the cord by embolism, or of drainage by compression of the caudal vena cava, e.g. in horses during prolonged dorsal recumbency under general anesthesia in pigs due to fibrocartilaginous emboli, probably originating in injury to the nucleus pulposus of an intervertebral disk.

PATHOGENESIS
The lesion may consist of disruption of nervous tissue or its compression by displaced bone or hematoma. Minor degrees of damage may result in local edema or hyperemia, or, in the absence of macroscopic lesions, transitory injury to nerve cells, classified as concussion. The initial
response is that of spinal shock, which affects a variable number of segments on both sides of the injured segment and is manifested by complete flaccid paralysis. The lesion must affect at least the ventral third of the cord before spinal shock occurs. When the shock wears off, the effects of the residual lesion remain. These may be temporary in themselves and completely normal function may return as the edema or the hemorrhage is resorbed. In sheep, extensive experimental damage to the cord may be followed by recovery to the point of being able to walk, but not sufficiently to be of any practical significance.

Traumatic lesions usually affect the whole cross-section of the cord and produce a syndrome typical of complete transection. Partial transection signs are more common in slowly developing lesions. Most of the motor and sensory functions can be maintained in 3-month-old calves with experimental left hemisection of the spinal cord.

In a retrospective study of dystocia-related vertebral fractures in neonatal calves, all the fractures were located between the 11th thoracic vertebra and the fourth lumbar vertebra, with 77% occurring at the thoracolumbar junction. All but one case was associated with a forced extraction using unspecified (53%), mechanical (28%) or manual (17%) methods of extraction. Traction is most commonly applied after the fetus has entered the pelvic canal. Manual traction varies from 75 kg pressure applied by one man to 260 kg applied by three or more men. The forces applied in mechanical traction vary from 400 kg for a calf puller to over 500 kg for a tractor. The transfer of these forces to the vertebrae and to the phyleal plates at the thoracolumbar junction could readily cause severe tissue damage. In a prospective study of vertebral fractures in newborn calves, all fractures were located at the thoracolumbar area, especially the posterior epiphysis of T13.

**CLINICAL FINDINGS**

Spinal shock develops immediately after severe injury and is manifested by flaccid paralysis (reflex loss) caudal to a severe spinal cord lesion. There is a concurrent fall in local blood pressure due to vasodilatation and there may be local sweating. Stretch and flexor reflexes and cutaneous sensitivity disappear but reappear within a half to several hours, although hypotonia may remain. The extremities are affected in most cases and the animal is unable to rise and may be in sternal or lateral recumbency. The muscles of respiration may also be affected, resulting in interference with respiration. The body area supplied by the affected segments will eventually show flaccid paralysis, disappearance of reflexes and muscle wasting—a lower motor neuron lesion.

When the injury is caused by invasion by parasitic larvae there is no stage of spinal shock but the onset is acute, although there may be subsequent increments of paralysis as the larva moves to a new site.

Neonatal calves with dystocia-related vertebral fractures are weak immediately after birth or remain recumbent and make no effort to rise.

Sensation may be reduced at and caudal to the lesion and hyperesthesia may be observed in a girdle-like zone at the cranial edge of the lesion as a result of irritation of sensory fibers by local inflammation and edema. Because of interference with the sacral autonomic nerve outflow there may be paralysis of the bladder and rectum, although this is not usually apparent in large animals. The vertebral column should be examined carefully for signs of injury. Excessive mobility, pain on pressure, and malalignment of spinous processes may indicate bone displacements or fractures. Rectal examination may also reveal damage or displacement particularly in fractures of vertebral bodies and in old bulls with spondylolisthesis.

Residual signs may remain when the shock passes off. This usually consists of paralysis, which varies in extent and severity with the lesion. The paralysis is apparent caudal to and at the site of the lesion. The reflexes return except at the site of the lesion. There is usually no systemic disturbance but pain may be sufficiently severe to cause an increase in heart rate and prevent eating.

Recovery may occur in 1–3 weeks if nervous tissue is not destroyed but when extensive damage has been done to a significantly large section of the cord there is no recovery and disposal is advisable. In rare cases animals that suffer a severe injury continue to be ambulatory for up to 12 hours before paralysis occurs. In such instances it may be that a fracture occurs but displacement follows at a later stage during more active movement. Recovered animals may be left with residual nervous deficits or with postural changes such as torticolis.

**Fracture of the cervical vertebrae in horses**

In horses fracture/dislocation of cranial cervical vertebrae occurs fairly commonly. Affected animals are recumbent and unable to lift the head from the ground. However, they may be fully conscious and able to eat and drink. It may be possible to palpate the lesion, but a radiograph is usually necessary. Lesions of the caudal cervical vertebrae may permit lifting of the head but the limbs are not moved voluntarily. In all cases the tendon and withdrawal reflexes in the limbs are normal to supernormal.

**Spondylosis in bulls**

Old bulls in artificial insemination centers develop calcification of the ventral vertebral ligaments and subsequent spondylitis or rigidity of the lumbar area of the vertebral column. When the bull ejaculates vigorously the calcified ligaments may fracture and this discontinuity may extend upward through the vertebral body. The ossification is extensive, usually from about T2–L3, but the fractures are restricted to the midlumbar region. There is partial displacement of the vertebral canal and compression of the cord. The bull is usually recumbent immediately after the fracture occurs but may rise and walk stiffly several days later. Arching of the back, slow movement, trunk rigidity and sometimes unilateral lameness are characteristic signs. Less severe degrees of spondylolisthesis have been recorded in a high proportion of much younger (2–3-year old) bulls, but the lesions do not appear to cause clinical signs.

**CLINICAL PATHOLOGY**

Radiologic examination may reveal the site and extent of the injury. CSF obtained from the lumbarosacral space may reveal the presence of red blood cells, suggesting pre-existing hemorrhage.

**Necropsy findings**

The abnormality is always visible on macroscopic examination. In dystocia-related vertebral fractures, hemorrhage around the kidneys, around the adrenal glands and in the perivertebral muscles is a common finding and a useful indicator that a thoracolumbar fracture is present. In addition to the vertebral fracture, subdural and epidural hemorrhage, myelomalacia, spinal cord compression, severed spinal cord, and fractured ribs are common findings.

**Differential diagnosis**

Differentiation from other spinal cord diseases is usually not difficult because of the speed of onset and the history of trauma, although spinal myelitis and meningitis may also develop rapidly. Other causes of recumbency may be confused with trauma especially if the animal is not observed in the immediate preclinical period. In most diseases characterized by recumbency, such as azoturia, acute rumen impaction and acute coliform mastitis, there are other signs to indicate the existence of a lesion other than spinal cord trauma. White muscle disease in foals is characterized by weakness and the serum creatine kinase activity will be increased.
TREATMENT
Treatment is expectant only, surgical treatment rarely being attempted. Large doses of corticosteroids or nonsteroidal anti-inflammatory agents are recommended to minimize the edema associated with the spinal cord injury. Careful nursing on deep bedding with turning at 3-hourly intervals, massage of bony prominences and periodic slinging may help to carry an animal with concussion or other minor lesion through a long period of recumbency. In cattle especially, recumbency beyond a period of about 48 hours is likely to result in widespread necrosis of the caudal muscles of the thigh and recovery in such cases is improbable. A definitive diagnosis of a vertebral fracture with paralysis usually warrants a recommendation for euthanasia.

REVIEW LITERATURE

REFERENCES

SPINAL CORD COMPRESSION
The gradual development of a space-occupying lesion in the vertebral canal produces a syndrome of progressive weakness and paralysis. A pre-existing inflammatory or neoplastic lesion of the vertebrae may result in spontaneous fracture of the vertebral body and compression of the spinal cord.

ETIOLOGY
Compression of the spinal cord occurs from space-occupying lesions in the vertebral canal, the common ones being as follows.

Tumors
The most commonly occurring tumor in animals is lymphosarcoma, which the nerve trunks and invades the vertebral canal, usually in the lumbosacral region and less commonly in the brachial and cervical areas. This tumor is particularly common in adult cattle with multicentric lymphosarcoma due to bovine leukemia virus infection.

Rare tumors include: fibrosarcomas, metastases, plasma cell myeloma, angiosarcoma, melanoma in a horse,1 hemangiosarcoma in a horse,2 neurofibroma and lymphosarcoma, e.g., in horses, vascular hamartoma in a goat.3

Vertebral body or epidural abscess
Vertebral body abscesses (osteomyelitis) occur most commonly in neonatal farm animals generally in association with a chronic supplicative lesion elsewhere in the body.

- Docking wounds in lambs, bite wounds in pigs and chronic supplicative pneumonia in calves are common occurrences
- Polyradiculitis and endocarditis may also be present
- Compression of the spinal cord is caused by enlargement of the vertebral body abscess into the vertebral canal and there may or may not be deviation of the vertebral canal and its contents
- The original site of infection may have resolved when the clinical signs referable to the spinal cord abscess appear
- Hematogenous spread may also occur from Arcanobacterium (Actinomyces or Corynebacterium) pyogenes in cattle, Actinomyces bovis in cattle with lumpy jaw, Corynebacterium pseudotuberculosis in sheep
- Epidural abscesses causing compression of the spinal cord and not associated with vertebral bodies also occur in lambs.4

Bony lesions of vertebra
- Exostoses over fractures with no displacement of vertebral bodies
- Similar exostoses on vertebral bodies of lambs grazing around old lead mines
- Hypovitaminosis A in young growing pigs causing compression of the nerve roots passing through the vertebral foramina
- Congenital deformity or fusion of the atlanto-occipital-axial joints in calves, foals and goats (see Congenital defects, below)
- Congenital spinal stenosis of calves.5

Rarely there is protrusion of an intervertebral disc, identifiable by myelogram, and progressive paraparesis and ataxia also occur rarely in diskospondylitis in horses. Cervical pain is a more common sign in the latter. The degenerative lesions in disks in the neck of the horse resemble the Hansen type 2 disk prolapses in dogs.

Adult sows and boars
Adult sows and boars may have degeneration of intervertebral disks and surrounding vertebral osteophytes. Less commonly ankylosing spondylitis, arthritis of articular facets, defects in annulus fibrosus and vertebral end plates, and vertebral osteomyelitis or fracture. These lesions of diskospondylitis cause lameness in boars and sows rather than compression of cord and paralysis.

These are not to be confused with the many extravertebral causes of posterior lameness or paralysis in adult pigs, which are discussed in Chapter 13 on the musculoskeletal system.

Vertebral subluxation
Cervicothoracic vertebral subluxation in Merino sheep in Australia.6

Ataxia in horses
This is a major problem and is dealt with more extensively under the heading of enzootic incoordination of horses. For purposes of comparison the diseases involved are listed here:

- Nonfatal fractures of the skull (basiliphenoid, basiocippital, and petrous temporal bones)
- Nonfatal cervical fractures
- Atlanto-occipital instability
- Stenosis of cranial vertebral orifice of C3-C7,7 this may be effective as a compression mechanism only if the vertebrae adopt exaggerated positions
- Abnormal growth of interarticular surfaces
- Dorsal enlargement of caudal vertebral epiphyses and bulging of intervertebral disks
- Formation and protrusion of false joint capsules and extraosynovial bursae
- Spinal myelitis due to parasitic invasion or equine herpesvirus-1 virus, even loping-ill virus and probably others
- Spinal abscess usually in a vertebral body
- Cerebellar hypoplasia – most commonly the inherited version in Arabian foals
- Degenerative myelomalacia/myelopathy – cause unknown
- Fusion of occipital bone with the atlas, which is fused with the axis
- Hypoxic-ischemic neuropathy in aortic-iliac thrombosis
- Tumors of the meninges.

PATHOGENESIS
The development of any of the lesions listed above results in the gradual appearance of motor paralysis or hypoesthesia, depending on whether the lesion is ventrally or dorsally situated. In most cases there is involvement of all motor and sensory tracts but care is necessary in examination if the more bizarre lesions are to be accurately diagnosed. There may be hemiparesis or hemiplegia if the lesion is laterally situated. Paraparesis or paraplegia is caused by a bilateral lesion in the thoracic or lumbar cord and monoplegia by a unilateral lesion in the same area. Bilateral lesions in the cervical region cause tetraparesis to tetraplegia (quadriplegia).

In horses with chronic compressive myelopathy (wobblers), compression of the spinal cord results in necrosis of white
matter, and some focal loss of neurons. With time, secondary wallerian-like fiber degeneration in ascending white matter tracts cranial to the focal lesion and in descending white matter tracts caudal to the lesion occurs. Astrocytic gliosis is a prominent and persistent alteration of the spinal cord of horses with chronic cervical compressive myelopathy and is associated with nerve fiber degeneration at the level of the compression and in well-delineated areas of ascending and descending nerve fiber tracts. It is possible that the persistent astrocytic gliosis may prevent, or slow, recovery of neurological function in affected horses.

**Vertebral osteomyelitis in young calves** occurs most commonly in the thoracolumbar vertebrae and less commonly in the cervical vertebrae. The abscess of the vertebral body gradually enlarges and causes gradual compression of the spinal cord, which causes varying degrees of paresis of the pelvic limbs and ataxia. The abscess may extend into adjacent intervertebral spaces and result in vertebral arthritis with lysis of the articular facets. The onset of paresis and paralysis may be sudden in cases of abscessation or osteomyelitis of the vertebrae, which may fracture and cause displacement of bony fragments into the vertebral canal with compression and traumatic injury of the spinal cord. Vertebral body abscesses between T2 and the lumbar plexus will result in weakness of the pelvic limbs and normal flexor withdrawal reflexes of the pelvic limbs. Lesions at the site of the lumbar plexus will result in flaccid paralysis of the pelvic limbs.

**CLINICAL FINDINGS**

Varying degrees of progressive weakness of the thoracic limbs or pelvic limbs may be the initial clinical findings. With most lesions causing gradual spinal cord compression, difficulty in rising is the first sign, then unsteadiness during walking due to weakness, which may be more marked in one of a pair of limbs. The toes are dragged along the ground while walking and the animal knuckles over on the fetlocks when standing. Finally the animal can rise only with assistance and then becomes permanently recumbent. These stages may be passed through in a period of 4–5 days.

The paralysis will be flaccid or spastic depending on the site of the lesion and reflexes will be absent or exaggerated in the respective states. The ‘dog-sitting’ position in large animals is compatible with a spinal lesion caudal to the second thoracic vertebral segment. Calves with vertebral osteomyelitis caudal to T2 are usually able to sit up in the ‘dog-sitting’ position, they are bright and alert and will suck the cow if held up to the teat. In some cases, extensor rigidity of the thoracic limbs resembles the Schiff–Sherrington syndrome and indicates a lesion of the thoracic vertebrae.

Lesions involving the lumbar plexus will result in flaccid paralysis of the pelvic limbs and an absence of the flexor withdrawal reflexes. Lesions involving the sacrococcygeal vertebrae will cause a decrease in tail tone, decreased or absent perineal reflex and urinary bladder distension.

**Pain and hyperesthesia** may be evident before motor paralysis appears. The pain may be constant or occur only with movement. In vertebral body osteomyelitis in the horse, vertebral column pain and a fever may be the earliest clinical abnormalities. With neoplasms of the epidural space, the weakness and motor paralysis gradually worsen as the tumor enlarges.

**Considerable variation** in signs occurs depending on the site of the lesion. There may be local hyperesthesia around the site of the lesion and straining to defecate may be pronounced. Retention of the urine and feces may occur. There is usually no detectable abnormality of the vertebral body on physical examination.

**In the wobbler horse,** circumduction of the limbs with ataxia is typical. The ataxia is usually pronounced in the pelvic limbs, and weakness is evident by toe dragging and the ease with which the horse can be pulled to one side while walking. Ataxia with hypotonia is often evident in the thoracic limbs, especially while walking the horse on a slope and with the head elevated.

**Calves** with congenital spinal stenosis are usually unable to stand or can do so only if assisted. There are varying degrees of weakness and ataxia of the pelvic limbs. They are bright and alert and will suck the cow if assisted. Those that survive for several weeks will sometimes assume the ‘dog-sitting’ position.

**CLINICAL PATHOLOGY**

Radiographic examination of the vertebral column should be carried out if the animal is of a suitable size. Myelography is necessary to demonstrate impingement on the spinal cord by a stenotic vertebral canal. Myelography using the contrast medium Iopamidol has been done in neonatal calves for the detection of spinal cord compression causing paresis. The contrast medium was introduced through the foramen magnum under general anesthesia.

The cerebrospinal fluid may show a cellular reaction if there is some invasion of the spinal canal.

**NECROPSY FINDINGS**

Gross abnormalities of the vertebrae and the bony spinal canal are usually obvious. Those diseases of the spinal cord characterized by degeneration without gross changes require histological techniques for a diagnosis.

**DIFFERENTIAL DIAGNOSIS**

Differentiation between abscess, tumor and exostoses in the vertebral canal is usually not practicable without radiographic examination. Vertebral osteomyelitis is difficult to detect radiographically, particularly in large animals, because of the overlying tissue. In bovine lymphosarcoma there are frequently signs caused by lesions in other organs. A history of previous trauma may suggest exostosis. The history usually serves to differentiate the lesion from acute trauma.

- Spinal myelitis, myelomalacia and meningitis may resemble cord compression but are much less common. They are usually associated with encephalitis, encephalomalacia and cerebro menigitis respectively
- Meningitis is characterized by much more severe hyperesthesia and muscle rigidity
- Rabies in the dumb form may be characterized by a similar syndrome but ascends the cord and is fatal within a 6-day period.

In the newborn there are many congenital defects in which there is defective development of the spinal cord. Most of them are not characterized by compression of the cord, the diminished function being caused in most cases by an absence of tissue. Spina bifida, syringomyelia and dysraphism are characterized by hindquarter paralysis or, if the animal is able to stand, by a wide-based stance and overextension of the legs when walking. Some animals are clinically normal.

A generalized degeneration of peripheral nerves such as that described in pigs and cattle causes a similar clinical syndrome; so does polyradiculoneuritis.

A nonsuppurative ependymitis, meningitis and encephalomyelitis, such as occurs in equine infectious anemia, may also cause an ataxia syndrome in horses.

**Paresis or paralysis of one limb** (monoplegia) is caused by lesions in the ventral gray matter, nerve roots, brachial and lumbosacral plexus, and peripheral nerves and muscles of the limbs.

**TREATMENT**

Successful treatment of partially collapsed lumbar vertebrae by dorsal laminectomy has been performed in a calf and in horses, but in farm animals treatment is usually not possible and in most cases slaughter for salvage is recommended.
The subject of back pain, and its relationship to lameness, is a very important one in horses. There is often a lesion in the vertebral canal and by pressing on the cord or peripheral nerves it causes gait abnormalities that suggest the presence of pain, or they actually cause pain. Spondylosis, injury to dorsal spinous processes, and sprain of back muscles are common causes of the same pattern of signs. Because these problems are largely orthopedic ones, and therefore surgical, their exposition is left to other authorities.

It is necessary in horses to differentiate spinal cord lesions from acute nutritional myostyrophy, and subacute tying-up syndrome. Those diseases are characterized by high serum creatine kinase and aspartate aminotransferase activities.

**MYELITIS**

Inflammation of the spinal cord is usually associated with viral encephalitis. The signs are referable to the loss of function, although there may be signs of irritation. For example, hyperesthesia or paresthesia may result if the dorsal root ganglia are involved. This is particularly noticeable in pseudorabies and in enzootic ataxia. There is widespread degeneration of the white matter. Appetites remain normal, but there is no evidence of cranial nerve, cerebral or cerebellar involvement clinically. Abnormal gait and posture are evident, usually initially in the pelvic but eventually also in the thoracic limbs. There are no gross lesions but histologically there is degeneration of neuronal processes in the white matter of all spinal cord tracts. Myelomalacia is most severe in the thoracic segments. The disease is progressive and there is no known treatment.

**Sporadic cases of degeneration of spinal tracts have been observed in pigs.** One outbreak is recorded in the litter of sow on lush clover pasture. The piglets were unable to stand, struggled violently on their sides with rigid extension of the limbs and, although able to drink, usually died of starvation. Several other outbreaks in pigs have been attributed to selenium poisoning.

An inherited lower motor neuron disease of pigs has been recorded. Clinical findings of muscular tremors, paresis or ataxia developed at 12–59 days of age. There is widespread degeneration of myelinated axons in peripheral nerves and in the lateral and ventral columns of lumbar and cervical segments of the spinal cord. Axonal degeneration is present in ventral spinal nerve roots and absent in dorsal spinal nerve roots when sampled at the same lumbar levels.

**Equine degenerative myeloneuropathy** of unknown etiology affects young horses and has been recorded in the USA, Canada, the UK, and Australia. The major clinical signs are referable to bilateral leukomyelopathy involving the cervical spinal cord. There is abnormal positioning and decreased strength and spasticity of the limbs as a result of upper motor neuron and general proprioceptive tract lesions. Hypalgnesia, hypotonia, hypesthesia, muscle atrophy, or vestibular signs are not present and there is no evidence of cranial nerve, cerebral or cerebellar involvement clinically. Abnormal gait and posture are evident, usually initially in the pelvic but eventually also in the thoracic limbs. There are no gross lesions but histologically there is degeneration of neuronal processes in the white matter of all spinal cord tracts, especially the dorsal spinocerebellar and ulcomarginal tracts. The lesion is most severe in the thoracic segments. The disease is progressive and there is no known treatment.

**Equine motor neuron disease** affects horses from 15 months to 25 years of age of many different breeds. Progressive weakness, short-striding gait, trembling, long periods of recumbency, and trembling and sweating following exercise are characteristic clinical findings. The weakness is progressive and recumbency is permanent. Appetites remain normal or become excessive. At necropsy, degeneration and/or loss of somatic motor neurons in the spinal ventral horns and angular atrophy of skeletal muscle fibers are characteristic.

**REFERENCES**

Sporadic cases of spinal cord damage in horses include hemorrhagic myelo-
malacia following general anesthesia and acute spinal cord degeneration fol-
lowing general anesthesia and surgery. Following recovery from the anesthesia,
the horse is able to assume sternal recumbency but not able to stand. A
hemorrhagic infarct assumed to be due to cartilage emboli, and a venous mal-
formation causing spinal cord destruction have also occurred in the horse. The
disease must be differentiated from myelitis and spinal cord compression caused by space-occupying lesions of the vertebral canal, and cervical, vertebral
malformation/malarticulation.

Diseases of the peripheral nervous system

The peripheral nervous system consists of cranial and spinal nerve components. As such, the peripheral nervous system includes the dorsal and ventral nerve roots, spinal ganglia, spinal and specific peripheral nerves, cranial nerves and their sensory ganglia, and the peripheral components of the autonomic nervous system.

ETIOLOGY

There are several different causes of peripheral nervous system disease.

Inflammatory

Polyneuritis equi, also known as neuritis of the cauda equina or cauda equina syndrome, is a rare and slowly progressive demyelinating granulomatous disease affecting peripheral nerves in the horse. Polyneuritis equi is char-
acterized by signs of lower motor neuron lesions, primarily involving the perineal region but also affecting other peripheral nerves, especially the 5th and 7th cranial nerves. The 8th, 9th, 10th and 12th cranial nerves also may be involved. Clinical signs of perineal region paresis/paralysis pre-
dominate, manifest as varying degrees of hypoesthesia, hypalgesia and hyporeflexia of the tail, anus and perineal region. Degrees of urinary bladder paresis and rectal dilata-
tion are also present. Differential diagnoses include sacral or coccygeal trauma,
equine herpes myeloencephalopathy, equine protozoal myeloencephalitis, rabies and equine motor neuron disease.

Cranial neuritis with guttural pouch mycosis and enpyema in the horse may cause abnormalities of swallowing, laryngeal hemiplegia and Homer's syndrome if the glossopharyngeal and vagal nerves are involved in the inflam-
atory process of the guttural pouch.

Degenerative

Equine laryngeal hemiplegia, often called roaring, is a common disease of the horse in which there is paralysis of the left cricoarytenoid dorsalis muscle resulting in an inability to abduct the arytenoid cartilage and vocal fold, which causes an obstruction in the airway during inspiration. Endoscopic examina-
tion reveals asymmetry of the glottis. On exercise, inspiratory stridor develops as the airflow vibrates a slack and adducted vocal fold. The abnormality is due to idiopathic distal degeneration of axons in the left recurrent laryngeal nerve (see more details in Chapter 10).

Traumatic

Injection injuries to peripheral nerves may result from needle puncture, the drug deposited, pressure from an abscess or hematoma, or fibrous tissue around the nerve. Such injuries may result from needle puncture, the drug deposited, pressure from an abscess or hematoma, or fibrous tissue around the nerve. Injection injuries to peripheral nerves should only be used for postpartum calf paralysis.

Calving paralysis is common in heifers that have experienced a difficult calving. Affected animals are unable to stand without assistance; if they do stand, the hind limbs are weak and there is marked abduction and inability to adduct. It has always been erroneously thought that traumatic injury of the obturator nerves during passage of the calf in the pelvic canal is the cause of the paralysis; however, detailed pathological and experimental studies have demonstrated that most calving paralysis is due to damage to the sciatic nerve. Experimental transection of the obturator nerves does not result in paresis. The term obturator nerve paralysis should only be used for postpartum calf paralysis in heifers that do not have obturator nerve damage.

Degenerative

Experimental transection of the obturator nerves does not result in paresis. The term obturator nerve paralysis should only be used for postpartum calf paralysis.
Metabolic and nutritional
Pantothenic acid deficiency may occur in pigs fed diets based solely on corn (maize). Affected animals develop a goose-stepping gait due to degenerative changes in the primary sensory neurons of the peripheral nerves.

Toxic
Heavy metal poisoning including lead and mercury poisoning in horses has been associated with clinical signs of degeneration of peripheral cranial nerves but those are not well documented.

Tumors
A multicentric schwannoma causing chronic ruminal tympany and forelimb paresis has been recorded in an aged cow. Neoplastic masses were present throughout the body and both right and left brachial plexi were involved. The peripheral nerves of each brachial plexus were enlarged. Large tumor masses were present on the serosal surfaces of the esophagus, pericardial sac and epicardium, within the myocardium, endocardium and the ventral branches of the first four thoracic spinal nerves. A large mass was present in the anterior mediastinum near the thoracic inlet.

Autonomic nervous system
Grass sickness in the horse occurs exclusively in the UK and is characterized by a paracutaneous chronic alimentary tract disease of horses on pasture (hence the name). Gastrointestinal stasis is partial or complete. Paracutaneous cases are in shock and in a state of collapse with gastric refluxing. Acute, subacute and chronic cases also occur. Degenerative changes occur in the autonomic ganglia, especially the celiacomesenteric, stellate, thoracic sympathetic chain, ciliary, cranial and caudal cervical, the craniospinal sensory ganglia and selected nuclei in the central nervous system. The etiology is unknown.

REVIEW LITERATURE

REFERENCES

Congenital defects of the central nervous system
The pathogenesis of congenital defects, including those of the central nervous system, has been dealt with in general terms in Chapter 3. Inheritance, nutrition, virus infection in early pregnancy and some toxins can all play a part in the genesis of these defects and the purpose of this section is to guide the diagnostician through the recognition of the defect to the possible causes. However, many such cases occur sporadically and a specific cause cannot be identified. Although most developmental defects are present at birth there are a few that appear later in life, especially the abiotrophic diseases in which an essential metabolic process (essential that is for cellular structure and function) is missing and the tissue undergoes degeneration. The diseases to be identified are listed under the headings of the principal clinical signs and syndromes that they produce. Many affected neonates are weak and die either during birth or soon afterwards so that they tend to be diagnosed by pathologists rather than clinicians. There may be an unintentional bias toward more clinically conspicuous diseases in the following material. The reader is referred to the review literature for details of specific congenital defects.

Defects with obvious structural errors
- Hydrocephalus, sporadic or inherited, with obvious enlargement of the cranium
- Meningocele with protrusion of a fluid-filled sac through the open fontanelle in the cranial vault. The defect is inherited in some pigs
- Hydrocephalus with spina bifida combination – the Arnold-Chiari syndrome – in cattle
- Hydrocephalus with congenital achoondroplasia (bulldog calf syndrome)
- Cranial bifidum (may include meningocele) of pigs
- Ventral meningocele in a foal
- Microphthalmia – in microcephaly the cranial is usually of normal size
- Some cases of failure of closure of neural tube, e.g. spina bifida in lambs. There is a defect in the skin and dorsal arch of the vertebra in the lumbosacral area in some cases
- Exophthalmos with or without strabismus, an inherited form in Jersey and Shorthorn cattle does not appear until the animal is more than 6 months of age
- Neurofibromas occurring as enlargements on peripheral nerves and seen as subcutaneous swellings. They are passed from cow to calf
- Persistent cloaca and caudal spinal agenesis in calves
- Hydranencephaly, porencephaly and other structural defects due to intrauterine infection with Akabane, Bluetongue, Cache Valley and Wesselsbron viruses.

Diseases characterized by congenital paresis/paralysis
- Enzootic ataxia due to nutritional deficiency of copper. It may also develop later, within the first month of postnatal life
- Inherited congenital posterior paralysis of calves, and of pigs
- Congenital spinal stenosis of calves
- Spina bifida, sometimes accompanied by flexion and contracture of atrophy of hindlegs; most are stillborn. In rare cases the affected calf is ambulatory
- Spinal dysraphism in Charolais and Angus calves, syringomyelia and hydromyelia in calves
- Tetraparesis, tetraplegia, progressive ataxia with head deviation in foals with congenital occipitoatlanto-axial malformations. A familial tendency to the defects occurs in Arab and non-Arabian horses. Additional signs include stiffness of the neck, palpable abnormalities at the site and a clicking sound on passive movement. Foals may be affected at birth or develop signs later. The defect is identifiable radiographically
- A congenital dysplasia of the atlanto-occipital joint with excessive mobility is recorded in Angora goats and causes a compressive myelopathy. Devon calves may be affected by the same deformity and similar ones have been recorded in calves that were recumbent at birth and others in which ataxia developed subsequently
- More widespread malacic changes have been recorded in the spinal cord of calves but without the specific etiology being determined.

Neurogenic arthrogryposis and muscle atrophy
- Akabane virus infection of calves, kids, possibly lambs, in uterus
- There are many other causes of arthrogryposis listed under congenital abnormalities of joints but they are not known to be neurogenic.

Spasms of muscle masses
- Inherited spastic paresis (Elso-heel) of calves
Diseases characterized by cerebellar ataxia
- Inherited cerebellar hypoplasia of calves, Arabian foals, lambs
- Cerebellar hypoplasia and hypomyelination in calves from cows infected with BVD virus and possibly Akabane virus during pregnancy
- Cerebellar hypoplasia in piglets after hog cholera vaccination of dams
- Inherited cerebellar ataxia in pigs and foals
- Familial convulsions and ataxia of Angus cattle
- Mannosidosis of cattle
- Intracranial hemorrhage in newborn foals, discussed in more detail under Neonatal maladjustment syndrome
- Spinal cord hypoplasia in Akabane virus infection in ruminants.

Diseases characterized by tremor
- Congenital paraplegia and tremor of piglets
- Inherited congenital spasms of cattle
- Inherited neonatal spasticity (jersey and Hereford cattle) develops at 2–5 days old
- Border disease (hairy shakers) in lambs due to BVD virus
- Inherited neuraxial edema (now inherited congenital myoclonus) of polled Hereford cattle and congenital brain edema of Herefords
- Myoclonia congenita as a result of infection with hog cholera or Aujeszky’s disease viruses
- Tremor with rigidity due to hydranencephaly and porencephaly in calves infected in utero with BVD virus
- Shaker calves in Herefords.

Disease characterized by convulsions
- Brain injury during birth in calves and lambs
- Brain compression due to hypovitaminosis A in calves and pigs
- Neonatal maladjustment syndrome (barkers and wanderers) in Thoroughbred foals
- Congenital toxoplasmosis in calves, bluetongue virus infection in lambs
- Tetanic convulsion in inherited neuraxial edema (now inherited congenital myoclonus) of Hereford calves, but only when lifted to standing position
- Inherited idiopathic epilepsy of Brown Swiss cattle
- Familial convulsions and ataxia of Angus cattle
- Inherited narcolepsy/catalepsy in Shetland ponies and Suffolk horses (not really a convulsion)
- Doodler calves.

Diseases characterized by imbecility
- Microencephaly in calves, probably inherited, with no abnormality of the cranium, but the cerebral hemispheres, cerebellum and brainstem are reduced in size and the corpus callosum and fornix are absent
- Microencephaly recorded in sheep; many are dead at birth, viable ones are unable to stand, blind, incoordinate and have a constant tremor
- Anencephaly in calves with absence of cerebral hemispheres, rostral midbrain, occurs sporadically in calves
- Hydranencephaly associated with Akabane virus infection of calf, kid, and possibly lamb in utero
- Congenital porencephaly in lambs after intrauterine infection with bluetongue virus.

Ocular abnormalities
- Spontaneous microphthalmia and anophthalmia in calves, usually of unknown cause
- Congenital lenticular cataracts in cattle and lambs
- Blindness developing after birth in gangliosidosis of cattle and ceroid lipofuscinosis of sheep
- Constriction of optic nerve by vitamin A deficiency causing blindness in calves and pigs
- Constriction of optic nerve and blindness with BVD virus infection in calves in utero
- Inherited exophthalmos with strabismus of cattle
- Familial undulatory nystagmus (pendular nystagmus).

Defects conditioned by inheritance but not present at birth
- Cerebellar atrophy (abiotrophy) in calves and foals, a probably inherited cerebellar atrophy in sheep aged 3.5–6 years
- Inherited idiopathic epilepsy of Jerseys and Shorthorns
- Mannosidosis of cattle
- Gangliosidosis of cattle
- Bovine generalized glycosgenosis
- Multifocal symmetrical necrotizing encephalomyelopathy (Leigh’s disease) in Angus, Simmental, and Limousin cattle
- Globoid cell leukodystrophy of sheep
- Ceroid lipofuscinosis of sheep
- Inherited myotonia of goats
- Progressive ataxia of Charolais cattle
- Inherited citrullinemia of calves
- Inherited maple syrup urine disease.

REVIEW LITERATURE
Diseases of the musculoskeletal system

Principal manifestations of musculoskeletal disease

LAMENESS

Lameness is an abnormal gait or locomotion characterized by limping (claudication) or not bearing full weight on a leg, usually associated with pain in the musculoskeletal system. Lameness must be distinguished from ataxia, which is an abnormal gait characterized by lack of coordination of muscular action, usually because of a lesion of the central or peripheral nervous system.

Weakness is the inability to maintain a normal posture and gait, usually because of a lesion of muscle or generalized weakness due to an abnormal systemic state such as shock, hypocalcemia, or starvation.

Because of the difficulty inherent in the differentiation of diseases causing lameness, and other abnormalities of gait and posture, a summary is presented in Table 13.1. It does not include lameness in racing horses, which is described in textbooks on lameness in horses, or diseases of the nervous system that interfere with normal movement and posture. These are discussed in Chapter 12.

ABNORMAL POSTURE AND MOVEMENT

As a group, diseases of the musculoskeletal system are characterized by reduced activity in standing up and moving, and the adoption of unusual postures. Abnormal movements include limpness, sagging or stiffness and lack of flexion. Abnormal postures include persistent recumbency, including lateral recumbency. There may be signs of pain on standing, moving or palpation. There is an absence of signs specifically referable to the nervous system. For example, there are no signs of brain damage and the spinal cord reflexes are present but may be only partly elicitable (the sensory pathway is intact but the motor response may be diminished). Differentiation from diseases of the nervous system and from each other may be aided by specific biochemical, radiological or hematological findings that indicate the system involved. Specific epidemiological findings may indicate the location of the lesion (which may be secondary) in muscle, bones, or joints, as set out in Table 13.1.

DEFORMITY

Atypical disposition, shape or size of a part of the musculoskeletal system constitutes a deformity. This may occur in a number of ways, and be caused by the following.

Muscle and tendon defects

- Congenital hypermobility of joints, inherited and sporadic
- Congenital flexed or stretched tendons of limbs causing contracture of joints or hyperextension
- Inherited congenital splayleg of pigs
- Muscle hypertrophy (doppelender, culard) of cattle
- Acquired asymmetric hindquarters of pigs

Joint defects

- Inherited congenital ankylosis of cattle causing fixation of flexion
- Joint enlargement of rickets and chronic arthritis

Defects of the skeleton

- Dwarfism – inherited miniature calves, achondroplastic dwarves; short legs of inherited congenital osteopetrosis; nutritional deficiency of manganese; acorn calves
- Giant stature – inherited prolonged gestation, not really giantism, only large at birth
- Asymmetry – high withers, low pelvis of hyena disease of cattle
- Limbs – complete or partial absence, inherited or sporadic amputates; curvature of limbs in rickets; bowie or bentleg of sheep poisoned by Trachymene sp.
- Head – inherited and sporadic cyclopetan deformity; inherited probatocephaly (sheep’s head) of...

**SPONTANEOUS FRACTURES**

Spontaneous fractures occur uncommonly in farm animals and pre-existing diseases are usually present, which include the following:
- Nutritional excess of phosphorus causing osteodystrophia in horses
- Nutritional deficiency of calcium causing osteodystrophia in pigs
- Nutritional deficiency of phosphorus or vitamin D in ruminants causing rickets and/or osteomalacia; hypervitaminosis A may contribute to this
- Nutritional deficiency of copper
- Chronic fluoride intoxication.

**PAINFUL ASPECTS OF LAMENESS**

Musculoskeletal pain can be caused by lacerations and hematomas of muscle, myositis and space-occupying lesions of muscle. Osteomyelitis, fractures, arthritis, joint dislocations, sprains of ligaments and tendons are also obvious causes of severe pain. Among the most painful of injuries are swollen, inflammatory lesions of the limbs caused by deep penetrating injury or in cattle by extension from footrot. Amputation of a claw, laminitis and septic arthritis are in the same category. Ischemia of muscle and generalized muscle tetany, as occurs in electro-immobilization, also appear to cause pain.

Research on the pathophysiology and pharmacology of pain associated with lameness in animals indicates that the thresholds to painful stimuli change in response to pain and this change is seen as an indication of an alteration in nerve function or in nociceptive processing at higher levels. In flocks of sheep with severe lameness due to foot rot, affected sheep had a lower threshold to a mechanical nociceptive stimulus than matched controls and their thresholds remained low when tested 3 months later, after the apparent resolution of the foot lesions. Thus hyperalgesia persisted in severely lame sheep for at least 3 months. It is suggested that N-methyl-D-aspartate receptors are involved in the development of this long-term hypersensitivity. Similar findings have been reported in dairy heifers affected with claw lesions during the peripartum period.

**Relief of musculoskeletal pain**

Several aspects about relieving pain in agricultural animals are important. Cost has always been a deterrent to the use of local anesthetics and analgesics but, with changing attitudes, the need to control pain is more apparent. Treatment of the causative lesion is a major priority but the lesion may be painful for varying lengths of time. Relief and the control of pain should be a major consideration. Details on the use of analgesics are presented in Chapter 2.

**ECONOMICS OF LAMENESS IN FOOD-PRODUCING ANIMALS**

Diseases of the musculoskeletal system and feet that cause lameness cause major economic losses. A survey of the incidence and prevalence of lameness in cattle on 37 dairy farms in the UK in 1989–91 found a mean annual incidence of 54.6 new cases per 100 cows (farm range 11–170%) and a mean annual prevalence of 21% (farm range 2–54%).

Loss of production occurs because animals that are in pain have difficulty moving around and do not eat and milk normally. Reproductive performance may be reduced because of failure to come into heat normally. The culling rate may be higher than is desirable because so many of the lesions of the feet and legs are incurable. The direct monetary costs for the treatment of lame animals are not high, but the actual treatment of either individual animals or groups of animals is time-consuming and laborious. The condemnation of animals to slaughter because of lameness is hence more difficult.

The epidemiological factors which contribute to lameness include:
- Injuries due to floor surfaces
- Persistently wet, unhygienic ground conditions
- Overcrowding and trampling during transportation and handling
- Nutritional inadequacies
- Undesirable skeletal conformation
- Failure to provide regular foot-trimming

Certain breeds may be more susceptible to these diseases of the feet and legs than others. Osteoarthritis occurs most commonly in old animals. Diseases of the legs of dairy cattle occur most commonly at the time of parturition and during the first 50 days of lactation. Diseases of the feet of dairy cattle occur most commonly in days 50–150 of the lactation period. Often the etiology is complex and a definitive etiological diagnosis cannot be made. This makes clinical management difficult and often unrewarding.

**REFERENCES**

**EXAMINATION OF THE MUSCULOSKELETAL SYSTEM**

The clinical examination of the musculoskeletal system and the feet of farm animals would include the following special examinations.

**Analysis of gait and conformation**

Inspection of the gait of the animal is necessary to localize the site of lameness. Evaluation of its conformation may provide clues about factors that may contribute to lameness. Details on the examination of farm animals for lameness are available in textbooks on lameness in horses and cattle.

**Close physical examination**

A close detailed physical examination of the affected area is necessary to localize the lesion. This includes passive movements of limbs to identify fractures, dislocations and pain on movement. Muscles can be palpated for evidence of enlargement, pain, or atrophy.

**Radiography**

Radiography is useful for the diagnosis of diseases of bones, joints and soft tissue swelling of limbs, which cannot be easily defined by physical examination. Detailed radiographic information about the joint capsule, joint cavity or articular cartilage can be obtained using negative (air), positive or double contrast arthrography. Ultrasonographic imaging can be used to differentiate the pathological changes in the soft tissue structures of digital flexor tendon sheaths of cattle.

**Ultrasoundography**

Ultrasoundography is used extensively in dogs and horses for the visualization of soft tissue structures of the joint. Most veterinary practices have an ultrasound machine that is used for small-animal imaging or transrectal pregnancy diagnosis in cattle and horses. Ultrasonography is cheaper, faster and provides important information compared to radiography; it is also less invasive and cheaper than joint fluid aspiration and analysis.

The ultrasonographic anatomy of the elbow, carpal, fetlock, and stifle joints of clinically normal sheep using a 7.5 MHz linear transducer with a stand-off pad has been described. The anatomical structures that could be consistently identified in normal ovine joints included bone, articular cartilage, ligaments and tendons. In sheep with chronic arthritis/synovitis, the gross thickening of the joint capsule is visible as a hyperechoic band up to 20 mm thick.

The ultrasonographic examination of the stifle region in cattle has been
described. The homogeneously echogenic patellar and collateral ligaments, the combined tendon of the long digital extensor and peroneus tertius muscles, the popliteal tendon, the anechoic articular cartilage of femoral trochlea, the echogenic menisci and the hyperechoic bone surfaces were imaged successfully. The boundaries of the joint pouches became partially identifiable only when small amounts of anechoic fluid were present in the medial and lateral femorotalial joint pouches. The main indication for ultrasonography of the bovine stifle is evaluation of acute septic and traumatic disorders of the region, when specific radiographic signs are often nonspecific or absent. The cruciate ligaments could not be imaged in live cattle. The cruciate ligaments are identifiable in the horse, in which flexion of the hind limbs is a routine procedure necessary for identification of these structures.

The ultrasonographic examination of the carpal region in cattle has been described. The main indication is the evaluation of septic and traumatic disorders of the carpal joints and tendon sheaths. Each tendon and tendon sheath in carpal region must be scanned separately. The use of a stand-off pad is recommended as it permits adaptation of the rigid transducer to the contours of the carpus. The carpal joint pouches and tendon sheath lumina are not clearly defined in healthy cattle. Thus the ability to image these structures indicates the presence of synovial effusion.

Ultrasonography is a valuable diagnostic aid for septic arthritis. Joint effusion, which is one of the earliest signs of septic arthritis, the accurate location of soft tissue swelling, the extent and character of joint effusion and involvement of concurrent periarticular synovial cavities or other soft tissue structures can be imaged by ultrasonography. The ultrasonogram can image the presence of small, hyperechoic fragments within the joint, appearing very heterogeneous. Normal synovial fluid is anechoic and appears black on the sonogram. A cloudy appearance is usually associated with the presence of pus.

Muscle biopsy
A muscle biopsy may be useful for microscopic and histochemical evaluations.

Arthrocentesis
Joint fluid is collected by needle puncture of the joint cavity (arthrocentesis) and examined for the presence of cells, biochemical changes in the joint fluid and the presence of infectious agents. The techniques and application of arthrocentesis for some of the joints commonly sampled in the horse have been reviewed.

Arthroscopy
Special endoscopes are available for inspection of the joint cavity and articular surfaces (arthroscopy). Diagnostic and surgical arthroscopy is now commonplace in specialized equine practice. Surgical arthroscopy is rapidly replacing conventional arthrotomy for the correction of several common surgical conditions of the musculoskeletal system of the horse. Accurate quantification of equine articular lesions is possible when the procedure is performed by an experienced arthroscopist. Convalesent time following surgery is decreased and the cosmetic appearance improved compared to arthrotomy. The arthroscopic anatomy of the intercarpal and radiocarpal joints of the horse have been described. A synovial membrane biopsy can be examined histologically and for infectious agents and may yield useful diagnostic information.

Serum biochemistry and enzymology
When disease of bone or muscle is suspected, the serum levels of calcium, phosphorus, alkaline phosphatase and the muscle enzymes creatine phosphokinase (CPK) and aspartate aminotransferase (AST), also known as serum glutamic oxaloacetic transaminase (SGOT), may be useful. The muscle enzymes are sensitive indicators of muscle cell damage; the serum levels of calcium, phosphorus and alkaline phosphatase are much less sensitive indicators of osteodystrophy.

Nutritional history
Because the most important osteodystrophies and myopathies are nutritional in origin a complete nutritional history must be obtained. This should include an analysis of the feed and determination of the total amount of intake of each nutrient, including the ratio of one nutrient to another in the diet.

Environment and housing
When outbreaks of lameness occur in housed cattle and pigs the quality of the floor must be examined to evaluate the possibility of floor injuries.

REFERENCES

Diseases of muscles

MYASTHENIA (SKELETAL MUSCLE ASTHENIA)
The differential diagnosis of paresis, paralysis and incoordination should include a consideration of skeletal muscle weakness unrelated to primary neurogenic hypotonia or to permanent muscle injury, including myopathy and myositis. Most of the syndromes that fall into this group of myasthenia have been described in detail elsewhere in this book and are referred to briefly here only to complete the list of abnormals of skeletal muscle that affect gait and posture. Unlike myopathy and myositis, they are reversible states.

The common causes of myasthenia in farm animals are:

- **Ischemia** in infar thrombosis in the horse and after recumbency in cows with parturient paresis. The end stage is myonecrosis and not reversible
- **Metabolic effect on muscle fibers** – causes include hypokalemia, hypocalcemia and possibly hypophosphatemia (in parturient paresis of dairy cows), hypomagnesemia (in lactation tetany), hypoglycemia of newborn pigs and lactic acidemia after engorgement on grain
- **Toxins** – general toxemia is a cause. Also, many plant toxins exert an effect on skeletal muscle activity. Although in most cases the mode of the action of the toxin is unknown, the toxins have been listed as neurotoxins.

**MYOPATHY**

The term myopathy describes the non-inflammatory degeneration of skeletal muscle that is characterized clinically by muscle weakness and pathologically by hyaline degeneration of the muscle fibers. The serum levels of some muscle enzymes are elevated and myoglobinuria is a common accompaniment.

**ETOLOGY AND EPIDEMIOLOGY**

The most important myopathies in farm animals are due to nutritional deficiencies of vitamin E and selenium and the effects of unaccustomed exercise. In humans, in contrast, the muscular dystrophies occur as inherited defects of muscle or degenerative lesions caused by interruption of their nerve supply. The skeletal myopathies can be classified into primary and secondary myopathies.

A retrospective analysis of the case records in a veterinary teaching hospital over a 9-year period revealed that the most common myopathy in horses was exercise-associated muscle disorder (69%). The remainder were postexhaustion syndrome (9%), infectious myopathies (10.5%), immunological myopathy (6.0%), nutritional myopathy (4.5%) and hyperkalemic periodic paralysis (1.5%).

The major causes of myopathy in farm animals and their epidemiological determinants are as follows.
Diseases of muscles

Enzootic nutritional muscular dystrophy
A nutritional deficiency of vitamin E and/or selenium is a common cause in young calves, lambs, foals, and piglets. Factors enhancing or precipitating onset include: rapid growth, highly unsaturated fatty acids in diet and unaccustomed exercise. The disease also occurs in adult horses.

Exertional or postexercise rhabdomyolysis
This is not known to be conditioned by vitamin E (selenium deficiency) and occurs as equine paralytic myoglobinuria (tying-up syndrome, azoturia) in horses after unaccustomed exercise or insufficient training. It also occurs in sheep chased by dogs, in cattle after running wildly for several minutes and as capture myopathy during capture of wildlife. An acute myopathy of undetermined etiology occurred in horses at grass in Scotland. The horses were not in training, creatine kinase levels were elevated and the urine was dark brown; most of them died after unaccustomed exercise or insufficient transportation, overcrowding and handling in

Toxic agents
This is caused by poisonous plants, including Cassia occidentalis, Karwinskia humboldtiana, Ixioena spp., Geigeria spp. and lupins. A special case is enzootic calcinosis of all tissues, especially muscle, and the principal signs are muscular, and is caused by poisoning by Solarium malacogylon, Tricetum spp., and Cestrum spp.

Myoglobinuria
Because of the necrosis of muscle, myoglobin is excreted in the urine and myoglobinuric nephrosis is an important complication, particularly of acute primary myopathy. The degree of myoglobinuria depends on the severity of the lesion, acute cases resulting in marked myoglobinuria, and on the age and species of animal affected. Adult horses with myopathy may liberate large quantities of myoglobin, resulting in dark brown urine. Yearling cattle with myopathy release moderate amounts and the urine may or may not be colored; calves with severe enzootic nutritional muscular dystrophy may have grossly normal urine. In all species the renal threshold of myoglobin is so low that discoloration of the serum does not occur.

Muscle enzymes
An important biochemical manifestation of myopathy is the increased release of muscle cell enzymes that occurs during muscle cell destruction. CPK and serum glutamic oxaloacetic transaminase are both elevated in myopathy and CPK, particularly, is a more specific and reliable indication of acute muscle damage. Increased amounts of creatinine are also released into the urine following myopathy.

Exertional rhabdomyolysis
In exertional rhabdomyolysis in horses there is enhanced glycolysis with depletion of muscle glycogen, the accumulation of large amounts of lactate in muscle and blood and the development of hyaline degeneration of myofibers. Affected muscle fibers are richer in glycogen in the acute stage of ‘tying-up’ than in the late stages, suggesting an increased glycogen storage in the early phase of the disease compared with normal healthy horses. During enforced exercise there is local muscle hypoxia and anaerobic oxidation
resulting in the accumulation of lactate and myofibrillar degeneration. The pathogenesis of postanesthetic myositis in horses is uncertain,6 a significant postischemic hyperemia occurs in horses that develop postanesthetic myopathy.6 Postanesthetic recumbency can occur in the horse with polysaccharide storage myopathy.7

Types of muscle fiber affected
In most animals skeletal muscle is composed of a mixture of fibers with different contractile and metabolic characteristics. Fibers with slow contraction times have been called slow twitch or type I fibers and those with fast contractile time are fast twitch or type II. Histochemically, types I and II fibers can be differentiated by staining for myofibrillar ATPase. Type II fibers can be subgrouped into type IIA and IIB on the basis of acid preincubations.8 Several different characteristics of these muscle fibers have been studied in the horse. There are variations in the percentage of each type of fiber present and in composition of muscle fibers dependent on genetic background, age, and stage of training.8 There are also variations in the muscle fibers within one muscle9 and between different muscles.10 The histochemical characteristics of equine muscle fibers have been examined:11,12

- Type I fibers are characterized by strong aerobic capacity, compared with type IIA
- Type IIA fibers are more glycolytic and have strong aerobic and moderate to strong anaerobic capacities.
- Type IIB fibers are characterized by a relatively low aerobic and a relatively high anaerobic capacity and are glycolytic.11

The histochemical staining characteristics of normal equine skeletal muscle have been examined and serve as a standard for comparison with data obtained from skeletal muscles with lesions.12

Secondary myopathy due to ischemia
In secondary myopathy due to ischemia there may be multiple focal areas of necrosis, which causes muscle weakness and results in an increase of muscle enzymes in the serum. The degree of regeneration with myofibers depends on the severity of the lesion. Some regeneration occurs but there is considerable tissue replacement. In aortic and iliac thrombosis in calves under 6 months of age the thrombosis results in acute-to-chronic segmental necrosis of some skeletal muscles and coagulation necrosis in others.13

Neurogenic atrophy of muscle
In neurogenic atrophy there is flaccid paralysis, a marked decrease in total muscle mass and degeneration of myofibers, with failure to regenerate unless the nerve supply is at least partially restored.

CLINICAL FINDINGS
The nutritional myopathies associated with a deficiency of vitamin E and/or selenium occur most commonly in young growing animals and may occur in outbreak form, particularly in calves and lambs. The details are presented under the heading of vitamin E and selenium deficiency.

Primary myopathy
In general terms, in acute primary myopathy there is a sudden onset of weakness and pseudoparalysis of the affected muscles, causing paresis and recumbency and, in many cases, accompanying respiratory and circulatory insufficiency. The affected animals will usually remain bright and alert but may appear to be in pain. The temperature is usually normal but may be slightly elevated in severe cases of primary myopathy. Cardiac irregularity and tachycardia may be evident, and myoglobinuria occurs in adult horses and yearling cattle. The affected skeletal muscles in acute cases may feel swollen, hard and rubbery but in most cases it is difficult to detect significant abnormality by palpation. Acute cases of primary myopathy may die within 24 hours after the onset of signs.

Acute nutritional myopathy
While acute nutritional myopathy in horses occurs most commonly in foals from birth to 7 months of age, acute dystrophic myodegeneration also occurs in adult horses. There is muscle stiffness and pain, myoglobinuria, edema of the head and neck, recumbency and death in a few days. A special occurrence of myopathy has been recorded in suckling Thoroughbred foals up to 5 months of age. The disease occurs in the spring and summer in foals running at pasture with their dams and is unassociated with excessive exercise. In peracute cases there is a sudden onset of dejection, stiffness, disinclination to move, prostration and death 3–7 days later. Lethargy and stiffness of gait are characteristic of less acute cases. There is also a pronounced swelling and firmness of the subcutaneous tissue at the base of the mane and over the gluteal muscles. There may be excessive salivation, desquamation of lingual epithelium and board-like firmness of the masseter muscles. The foals are unable to suck because of inability to bend their necks. Spontaneous recovery occurs in mild cases but most severely affected foals die.

Severe nutritional myopathy of the masseter muscles in a 6-year-old Quarter Horse stallion has been described.14 The masseter muscles were swollen and painful, and there was exophthalmos and severe chemosis with protrusion of the third eyelids. The mouth could be opened only slightly and masticatory efforts were weak. Serum enzymeology supported a diagnosis of nutritional muscular dystrophy, and the concentrations of vitamin E and selenium in the blood and feed were lower than normal.

Tying-up
In tying-up in horses there is a very sudden onset of muscle soreness 10–20 minutes following exercise. There is profuse sweating and the degree of soreness varies from mild, in which the horse moves with a short, shuffling gait, to severe, in which there is a great disinclination to move at all. In severe cases, horses are unable to move their hindlegs, and swelling and rigidity of the croup muscles develops. Myoglobinuria is common.

Postanesthetic myositis
In postanesthetic myositis affected horses experience considerable difficulty during recovery from anesthesia. Recovery is prolonged and when initial attempts are made to stand there is lumbar rigidity, pain and reluctance to bear weight.7 Some affected horses will be able to stand in within several hours if supported in a sling.7 The limbs may be rigid and the muscles firm on palpation. In severe cases the temperature begins to rise reminiscent of malignant hyperthermia. Other clinical findings include anxiety, tachycardia, profuse sweating, myoglobinuria and tachypnea. Death may occur in 6–12 hours. Euthanasia is the only course for some horses. In the milder form of the syndrome, affected horses are able to stand, but are stiff and in severe pain for a few days.

Exertional rhabdomyolysis
In horses, the clinical findings are variable and range from poor performance to recumbency and death. Signs may be mild and resolve spontaneously within 24 hours or severe and progressive.

The usual presentation is a young (2–5-year-old) female racehorse with recurrent episodes of stiff gait after exercise. The horse does not perform to expectation and displays a short-stepping gait that may be mistaken for lower leg lameness. The horse may be reluctant to move when placed in its stall, be apprehensive and anorexic, and frequently shift its weight. More severely affected horses may be unable to continue to exercise, have hard and painful
muscles (usually gluteal muscles), sweat excessively, be apprehensive, refuse to walk and be tachycardic and tachypneic. Affected horses may be hyperthermic. Signs consistent with abdominal pain are present in many severely affected horses. Deep red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses may be recumbent and unable to rise.

Many different manifestations of equine polysaccharide storage myopathy occur. All manifestations are related to dysfunction, which results in pain, weakness, segmental fiber necrosis, stiffness, spasm, atrophy or any combination of the above. The muscles most severely affected are the powerful rump, thigh and back muscles, including gluteals, semimembranosus, semitendinosus and longissimus.

In exertional rhabdomyolysis in sheep chased by dogs, affected animals are recumbent, cannot stand, appear exhausted and myoglobinuria is common. Death usually follows. A similar clinical picture occurs in cattle that have run wildly for several minutes.

Hyperkalemic periodic paralysis
Initially there is a brief period of myotonia with prolapase of the third eyelid. In severe cases, the horse becomes recumbent and the myotonia is replaced by flaccidity. Sweating occurs, and generalized muscle fasciculations are apparent, with large groups of muscle fibers contracting simultaneously at random. The animal remains bright and alert and responds to noise and painful stimuli. In milder cases, affected horses remain standing and generalized muscle fasciculations are prominent over the neck, shoulder and flank. There is a tendency to stand base- wide. When the horse is asked to move, the limbs may buckle and the animal appears weak. The horse is unable to lift its head, usually will not eat and may yawn repeatedly early in the course of an episode. The serum potassium levels are elevated above normal during the episodes.

Secondary myopathy due to ischemia
In secondary myopathy due to ischemia, e.g. the downer cow syndrome, the affected animal is unable to rise and the affected hindlegs are commonly directed behind the cow in the frogleg attitude. The appetite and mental attitude are usually normal. No abnormality of the muscles can be palpated. With supportive therapy, good bedding and the prevention of further ischemia by frequent rolling of the animal, most cows will recover in a few days.

In calves with aortic and iliac artery thrombosis there is an acute onset of paresis or flaccid paralysis of one or both pelvic limbs. Affected limbs are hypothermic and have diminished spinal reflexes and arterial pulse pressures. The diagnosis can be defined using angiography. Affected calves die or are euthanized because treatment is not undertaken.

Neurogenic atrophy
With neurogenic atrophy there is marked loss of total mass of muscle, flaccid paralysis, loss of tendon reflexes and failure of regeneration. When large muscle masses are affected, e.g. quadriceps femoris in femoral nerve paralysis in calves at birth, the animal is unable to bear normal weight on the affected leg.

Dystrophy of the diaphragmatic muscles
In dystrophy of the diaphragmatic muscles in adult Meuse–Rhine–Yssel cattle there is loss of appetite, decreased rumination, decreased eructation and recurrent bloat. The respiratory rate is increased with forced abdominal respirations, forced movement of the nostrils and death from asphyxia in a few weeks.

Severe diaphragmatic necrosis in a horse with degenerative myopathy due to polysaccharide storage myopathy has been described. Affected horses may have severe respiratory distress and respiratory acidosis, and do not respond to supportive therapy.

CLINICAL PATHOLOGY
Muscle-derived serum enzymes
The serum levels of the muscle enzymes are characterized by following myopathy due to release of the enzymes from altered muscle cell membranes. Creatine kinase (CK) is a highly specific indicator of both myocardial and skeletal muscle degeneration. Plasma CK activity is related to three factors: the amount and rate of CK released from an injured muscle into plasma, its volume of distribution and its rate of elimination.  

CK has a half-life of about 4–6 hours and, following an initial episode of acute myopathy, serum levels of the enzyme may return to normal within 3–4 days if no further muscle degeneration has occurred. Levels of AST are also increased following myopathy but, because the enzyme is present in other tissues such as liver, it is not a reliable indicator of primary muscle tissue degeneration.

Because AST has a longer half-life than CK, the levels of AST may remain elevated for several days following acute myopathy. The daily monitoring of both CK and AST levels should provide an indication of whether active muscle degeneration is occurring. A marked drop in CK levels and a slow decline in AST levels suggests that no further degeneration is occurring whereas a constant elevation of CK suggests active degeneration.

In acute nutritional muscular dystrophy in calves, lambs, and foals the CK levels will increase from normal values of below 100 IU/L to levels ranging from 1000–5000IU/L and even higher. The levels of CK in calves will increase from a normal of 50IU/L to approximately 5000IU/L within a few days after being placed outdoors followed by unconditioned exercise. There is some preliminary investigation into quantification of the amount of skeletal damage in cattle based on the amount of CK activity.

The measurement of serum levels of glutathione peroxidase is a useful aid in the diagnosis of myopathy due to selenium deficiency.

In downer cows with ischemic necrosis of the thigh muscles, the CK and AST levels will be markedly elevated and will remain elevated if muscle necrosis is progressive in cows that are not well bedded and rolled from side to side several times daily to minimize the degree and extent of ischemic necrosis.

High levels of CK (1000 IU/L and greater) usually indicate acute primary myopathy. Levels from 500–1000 IU/L may be difficult to interpret in animals recumbent for reasons other than primary myopathy. This will necessitate a careful reassessment of the clinical findings, history and epidemiology.

In horses with acute exertional rhabdomyolysis (paralytic myoglobinuria) the CK levels will range from 5000–10 000 IU/L. Following vigorous exercise in unconditioned horses, the CK and AST levels will rise as a result of increased cell membrane permeability associated with the hypoxia of muscles subjected to excessive exercise. Lactate dehydrogenase (LDH) has also been used as a biochemical measurement of the degree of physical work done by horses in training. With progressive training in previously unconditioned horses there is no significant change between rest and exercise in the levels of serum CK, AST, and LDH. In horses with postanesthetic myositis the CK levels may exceed 100 000 IU/L, the serum calcium is decreased and the serum inorganic phosphorus is increased. In naturally occurring cases of exertional rhabdomyolysis in horses the most consistent acid–base abnormality may be a hypochloremia rather than metabolic acidosis as has been assumed.

Muscle biopsy
Investigation of the structural and biochemical alterations of muscle tissue in myopathy include biopsy techniques that
have been described.\textsuperscript{3,17} Needle biopsies require a specialized Bergstrom muscle biopsy needle, which most practitioners do have on hand. Open biopsy is recommended in order to obtain a strip of muscle. Biopsy of either the semimembranosus or semitendinosus muscles, at a site between the base of the tail and the tuber ischium, provides an adequate sample. Muscle biopsy samples can be processed for either frozen section or routine formalin-fixed, paraffin-embedded sections. The frozen section is considered the gold standard.

Inclusions of periodic-acid–Schiff (PAS)-positive, amylase-resistant complex polysaccharide are abnormal and characteristic findings in muscle of equine polysaccharide storage myopathy.\textsuperscript{3}

Histochemical techniques can be used on muscle biopsies of horses with muscular disease and animals with congenital and inherited myopathies.\textsuperscript{4}

**Myoglobinuria**
Myoglobinuria is a common finding in adult horses with acute paralytic myoglobinuria but is not a common finding in acute nutritional muscular dystrophy in young farm animals, except perhaps in yearling cattle with acute muscular dystrophy. The myoglobinuria may be clinically detectable as a red or chocolate brown discoloration of the urine. This discoloration can be differentiated from that caused by hemoglobin by spectrographic examination or with the use of orthotoluidine paper strips. Urine becomes dark when myoglobin levels exceed 40 mg/dL of urine. Discoloration of the plasma suggests hemoglobinuria. Both myoglobin and hemoglobin give positive results for the presence of protein in urine. Porphyria causes a similar discoloration although this may not be evident until the urine has been exposed to light for some minutes. The coloration is lighter, pink to red rather than brown, and the urine is negative to the guaiac test and fluoresces with ultraviolet light. Creatinuria accompanies acute myopathy but has not been used routinely as a diagnostic aid.

**Electromyography** is a special technique for the evaluation of the degree of neurogenic atrophy.

**NECROPSY FINDINGS**
Affected areas of skeletal muscle have a white, waxy, swollen appearance like fish flesh. Commonly only linear strips of large muscle masses are affected and the distribution of lesions is characteristically bilaterally symmetrical. Histologically the lesion varies from a hyaline degeneration to a severe myonecrosis, with subsequently the disappearance of large groups of muscle fibers and replacement by connective tissue. Calcification of the affected tissue may be present to a mild degree in these cases.

The lesions in excretory rhabdomyolysis in the horse are of a focal distribution and consist of hyaline degeneration with insignificant inflammatory reaction and slight calcification. The degenerative changes affect primarily the fast twitch fibers, which have a low oxidative capacity and are used when the horse trots at very close to its maximum speed.

**DIFFERENTIAL DIAGNOSIS**
Most myopathies in farm animals occur in rapidly growing, young animals and are characterized clinically by a sudden onset of acute muscular weakness, and pain often precipitated by unaccustomed exercise. There may be evidence of a dietary deficiency of vitamin and selenium in the case of nutritional muscular dystrophy. A sudden onset of recumbency or stiffness in young farm animals that are bright and alert should arouse suspicion of acute muscular dystrophy. Primary myopathies are not common in adult cattle, sheep or pigs but myopathy secondary to recumbency for other reasons does occur.

Secondary myopathy due to aortic and iliac thrombosis in calves may be differentiated from other common causes of hindlimb paresis including traumatic injury to the spinal cord, spinal cord compression due to vertebral body abscess, nutritional muscular dystrophy, myositis and nerve damage due to trauma of intramuscular injections, and clostridial myositis.\textsuperscript{14}

The exertional myopathies in the horse in training are usually readily obvious. The CK levels are valuable aids to diagnosis. In special circumstances, such as neurogenic myopathy, muscle biopsy and electromyography may be useful additional diagnostic aids. The histological and histochemical staining characteristics of equine muscle have been described and serve as a standard for comparison with abnormal muscle.

Myositis may present a similar syndrome but is usually present as a secondary lesion in a clinically distinguishable primary disease or is accompanied by obvious trauma or toxemia.

**TREATMENT**
Vitamin E and selenium are indicated for the treatment of nutritional muscular dystrophy and the details are provided under that heading. The treatment of exertional rhabdomyolysis in horses has not been well defined because of the uncertain etiology, but enforced rest and the relief of pain, if necessary, seems logical. Supportive therapy for any case of myopathy, particularly severe cases in which there is persistent recumbency, consists of:

- Liberal quantities of thick bedding
- Removal from solid floors to softer ground
- Frequent turning from side to side to minimize secondary myopathy
- Provision of fluid therapy to prevent myoglobinuric nephrosis
- A palatable, nutritious diet.

With the exception of the sporadically occurring congenital and inherited myopathies of farm animals, all the nutritional and exertional myopathies are amenable to treatment if it is begun early and if adequate supportive therapy is provided.

In myopathies associated with systemic acidosis the use of a solution of sodium bicarbonate may be indicated. Dietary sodium bicarbonate at the rate of 2% of total dry matter intake has been used for the treatment of exertional rhabdomyolysis in a horse.\textsuperscript{18} Horses with postanesthetic myositis must be considered as critical care patients for 18–24 hours. Maintenance of adequate renal perfusion is vital. Large quantities of intravenous polyionic balanced electrolyte fluids (50–100 L) must be given over a 24-hour period. Dantrolene sodium at 4 mg/kg body weight (BW) given orally immediately upon recognition of clinical signs is efficacious.

**CONTROL**
The nutritional myopathies in farm animals can be satisfactorily prevented by the provision of adequate quantities of dietary vitamin E and selenium in the maternal diet during pregnancy or at the strategic times in postnatal life. The prevention of exertional myopathy in the horse depends on a progressive training program and avoidance of sudden unaccustomed exercise in animals that are in good body condition and have been inactive. Similarly, in general terms, the prevention of the porcine stress syndrome will depend on careful handling and transportation techniques combined with genetic selection of resistant pigs.

**REFERENCES**

**REVIEWS LITERATURE**
by deposition of bone in soft tissues. In traumatic injuries caused by penetration of foreign bodies into muscle masses, ultrasonography may be used to detect fistulous tracts and the foreign bodies.

Extensive damage to or loss of muscle occurs in screwworm and sometimes blowfly infestation, although the latter is more of a cutaneous lesion, and by the injection of necrotizing agents. For example, massive cavities can be induced in the cervical muscles of horses by the intramuscular injection of escharotic iron preparations intended only for slow intravenous injection. Similarly, necrotic lesions can result from the intramuscular injection of infected or irritant substances. Horses are particularly sensitive to tissue injury, or are at least most commonly affected. Some common causes are chloral hydrate, antimicrobials suspended in propylene glycol, and even antimicrobials alone in some horses.

Injection site clostridial infections in horses
Clostridial myositis, myonecrosis, cellulitis, and malignant edema are terms used to describe a syndrome of severe necrotizing soft tissue infection associated with *Clostridium* spp. Affected horses typically develop peracute emphysematous soft tissue swelling in the region of an injection or wound within hours of the inciting cause. It can occur following the intramuscular or inadvertent perivascular administration of a wide variety of commonly administered drugs. In a series of 37 cases, the lesion occurred within 6–72 hours of a soft-tissue injection in most cases and most were in the neck musculature. Aggressive treatment can be associated with a survival rate of up to 81% for cases due to *Clostridium perfringens* alone; survival rates for other *Clostridium* spp. are lower. A combination of a high dose of intravenous antibiotic therapy and surgical fenestration and debridement is the recommended approach to treatment.

Injection site lesions in cattle
Muscle lesions associated with injection sites in the cattle industry are a source of major economic loss because of the amount of trim required at slaughter. The presence of injection-site lesions in whole muscle cuts, such as the top sirloin and outside round, limits their use and value. The occurrence of injection-site lesions in muscle is among the top five quality challenges for both beef and dairy market cows and bulls. Because injection-site lesions are concealed in muscles and/or are under subcutaneous fat, they are seldom found during fabrication at the packing plant and appear instead during wholesale/retail fabrication or at the consumer level. In 1998, the National Animal Health Monitoring System found that 47% of producers and 37% of veterinarians administered intramuscular injections in the upper or lower rear leg of cows; the need for further educational effort is apparent.

Monitoring the frequency of injection-site lesions allows educational efforts of state and national beef quality assurance programs to evaluate, more definitively, management practices of producers that can be changed to minimize occurrence of these defects. Audits done at abattoirs between 1998 and 2000 in the USA indicate that the frequency of injection-site lesions has decreased but the need remains for educational programs and continued improvements in beef quality assurance practices among beef and dairy cattle producers. Historically, most intramuscular injections were given in the gluteals and the biceps femoris muscles, which are prime cuts of beef. Surveys of injection sites in beef cattle in North America have found lesions in a significant percentage of prime cuts of beef. Lesions consisting of clear scars and woody calluses are mature and probably originated in calfhood; scars with nodules or cysts are less mature, occurring later in the feeding period. It is now recommended that intramuscular injections be given in the cervical muscles. Reducing the incidence of injection site lesions requires that manufacturers of biological and antibiotic preparations develop less irritating formulations. Products should be formulated for subcutaneous use whenever possible and administered in the neck muscles, which are not prime cuts of beef.

The outcome of an intramuscular injection depends on the nature of the lesion produced. Myodegeneration following intramuscular injections of antibiotics in sheep results in full muscle regeneration within less than 3 weeks. Necrosis following the injection results in scar formation with encapsulated debris, which persists for more than a month and leaves persistent scar tissue.

An outbreak of myositis, lameness and recumbency occurred following the injection of water-in-adjuvanted vaccines into the muscles of the left and right hips of near-term pregnant beef cattle. Within 24 hours, some cattle were recumbent, some had nonweightbearing lameness and, within 10 days, 50% of the herd developed firm swellings up to 24 cm in vaccination sites. Histologically, granulomatous myositis with intralesional oil was present. The swellings resolved over a period of 6 months. The acute transient lameness was attributed to the use of two irritating biological vaccines in the hip muscles of cows near parturition.
Diseases of bones

OSTEODYSTROPHY

Osteodystrophy is a general term used to describe those diseases of bones in which there is a failure of normal bone development, or abnormal metabolism of bone that is already mature. The major clinical manifestations include distortion and enlargement of the bones, susceptibility to fractures and interference with gait and posture.

ETIOLOGY

The common causes of osteodystrophy in farm animals include the following:

Nutritional causes

- Calcium, phosphorus and vitamin D
- Absolute deficiencies or imbalances in calcium-phosphorus ratios in diets cause:
  - Rickets in young animals, e.g., growing lambs fed a diet rich in wheat bran
  - Absolute deficiencies of calcium
  - Beef calves on intensive rations with inadequate supplementation
  - Osteomalacia in adult ruminants.

Osteodystrophy fibrosa in the horse

- Occurs most commonly in animals receiving a diet low in calcium and high in phosphorus.

Osteodystrophy fibrosa in pigs

- Occurs as a sequel to rickets and osteomalacia, which may occur together in young growing pigs that are placed on rations deficient in calcium, phosphorus and vitamin D following weaning.

Copper deficiency
- Osteoporosis in lambs
- Epiphysitis in young cattle.

Other nutritional causes

- Inadequate dietary protein and general undernutrition of cattle and sheep can result in severe osteoporosis and a great increase in ease of fracture
- Chronic parasitism can lead to osteodystrophy in young growing ruminants
- Hypovitaminosis A and hyperparathyroidism can cause osteodystrophic changes in cattle and pigs
- Prolonged feeding of a diet high in calcium to bulls can cause nutritional hypercalcitominsh with replacement of trabecular bone in the vertebral and long bones with compact bone, and neoplasms of the ultimobranchial gland
- Multiple vitamin and mineral deficiencies are recorded as causing osteodystrophy in cattle. The mineral demands of lactation in cattle can result in a decrease in bone mineral content during lactation with a subsequent increase during the dry period.

Chemical agents

- Chronic lead poisoning is reputed to cause osteoporosis in lambs and foals
- Chronic fluoride poisoning causes the characteristic lesions of osteofluorosis, including osteoporosis and exostoses

Grazing the poisonous plants Setaria sphacelata, Cenchrus ciliaris, and Panicum maximum var. trichogloume causes osteodystrophy in horses

Enzootic calcinosis of muscles and other tissues is caused by the ingestion of Solanum malaccylon, Solanum torvum, Trisetum flavescens (yellow oat grass), and Cenchrus dactylarum, which exert a vitamin-D-like activity

Bowie or bentleg, a disease caused by poisoning with Trachymene glauca folia, is characterized by extreme outward bowing of the bones of the front limbs.

Inherited and congenital causes

- There are many inherited and congenital defects of bones of newborn farm animals, which are described, and discussed in detail in Chapter 34. In summary, these include:
  - Achondroplasia and chondrodystrophy in dwarf calves and some cases of prolonged gestation
  - Osteogenesis imperfecta in lambs and Charolais cattle. There is marked bone fragility and characteristic changes on radiological examination
  - Osteopetrosis in Hereford and Angus calves
  - Chondrodysplasia in Orthodox calves
- Inherited exostoses in horses; inherited thicklegs and inherited rickets of pigs, which are well-established entities.

Angular deformities of joints of long bones due to asymmetric growth plate activity are common in foals and are commonly repaired surgically. The distal radius and distal metacarpus are most often affected, the distal tibia and metatarsal less commonly. Physiologically immature foals subjected to exercise may develop compression-type fractures of the central or third tarsal bones. Some of these foals are born prematurely or are from a twin pregnancy. Retained cartilage in the distal radial physis of foals 3–7 days of age presents without apparent clinical signs.

Phyisits is dysplasia of the growth plate, characterized by an irregular border between the cartilage and the metaphyseal zone of ossification, an increase in the lateromedial diameter of the physis, and distoparaxial ossification fissures at the distoproximally oriented fissures at the medial aspect of the metaphysis, which originate at the physis. In some cases, these may result in bilateral tibial metaphyseal stress fractures in foals.

Abnormal modeling of trabecular bone has been recognized in prenatal and neonatal calves. Abnormalities included growth retardation lines and lattices, focal retention of primary spongiosa and the persistence of secondary spongiosa. Intrauterine infection with viruses such as bovine virus diarreah (BVD) may be a causative factor.

Physical and environmental causes

Moderate osteodystrophy and arthropathy may occur in rapidly growing pigs and cattle raised indoors and fed diets that contain adequate amounts of calcium, phosphorus and vitamin D. Those animals raised on slatted floors or concrete floors are more commonly affected and it is thought that traumatic injury of the epiphyses and condyles of long bones may be predisposing factors in osteochondrosis and arthrosis in the pig (leg weakness) and epiphysitis in cattle. Experimentally raising young calves on metal slatted floors may result in more severe and numerous lesions of the epiphysis than occurs in calves raised on clay floors. Total confinement rearing of lambs can result in the development of epiphysitis and limb deformities. However, the importance of weight-bearing injury as a cause of osteodystrophy in farm animals is still uncertain. In most reports of such osteodystrophy, all other known causes have not been eliminated.

Chronic osteodystrophy and arthropathy have been associated with undesirable conformation in the horse.

Vertebral exostoses are not uncommon in old bulls and usually affect the thoracic vertebrae (T2 and T12) and the lumbar vertebrae (L2–L3), which are subjected to increased pressure during the bending of the vertebrae while copulating. The exostoses occur mainly on the ventral aspects of the vertebrae, fusing them to cause immobility of the region. Fracture of the ossification may occur, resulting in partial displacement of the vertebral column and spinal cord compression. The disease is commonly referred to as spondylitis or vertebral osteochondrosis.
and also occurs less commonly in adult cows and in pigs. It is suggested that the anulus fibrosus degenerates and that the resulting malfunctioning of the disk allows excessive mobility of the vertebral bodies, resulting in stimulation of new bone formation. A similar lesion occurs commonly in horses and may affect performance, particularly in hurdle races and cross-country events. The initial lesion may be a degeneration of the intervertebral disk.

**Some types of growth plate defect** occur in young growing foals and these are considered to be traumatic in origin. Failure of chondrogenesis of the growth plate may be the result of crush injuries in heavy, rapidly growing foals with interruption of the vascular supply to the germinal cells of the growth plate. Asymmetric pressures due to abnormal muscle pull or joint laxity may slow growth on the affected side and result in limb angulation.

**Femoral fractures** occur in newborn calves during the process of assisted traction during birth. Laboratory compression of isolated femurs from calves revealed that the fracture configurations and locations are similar to those found in clinical cases associated with forced extraction. The breaking strength of all femurs fell within the magnitude of forces calculated to be created when mechanical devices are used to assist delivery during dystocia. It is suggested that the wedging of the femur in the maternal pelvis and resulting compression during forced extraction accounts for the occurrence of supracondylar fractures of the femur of calves delivered in anterior presentation using mechanical devices in a manner commonly used by veterinarians and farmers.

**Tumors**

**Osteosarcomas** are highly malignant tumors of skeletoblastic mesenchyme in which the tumor cells produce osteoid or bone. Osteosarcomas are the most common type of primary bone tumor in animals such as dogs and cats but are rare in horses and cattle. Most tumors of bone in large animals occur in the skull. A periosteal sarcoma on the scapula has been recorded in the horse and an osteosarcoma of the mandible in a cow.

**PATHOGENESIS**

Osteodystrophy is a general term used to describe those diseases of bones in which there is a failure of normal bone development, or abnormal metabolism of bone that is already mature. There are some species differences in the osteodystrophies that occur with dietary deficiencies of calcium, phosphorus, and vitamin D.

**Rickets**

Rickets is a disease of young growing animals in which there is a failure of provisional calcification of the osteoid plus a failure of mineralization of the cartilaginous matrix of developing bone. There is also failure of degeneration of growing cartilage, formation of osteoid on persistent cartilage with irregularity of osteochondral junctions and overgrowth of fibrous tissue in the osteochondral zone. Failure of provisional calcification of cartilage results in an increased depth and width of the epiphyseal plates, particularly of the long bones (humerus, radius and ulna and tibia) and the costal cartilages of the ribs. The uncalcified, and therefore soft, tissues of the metaphyses and epiphyses become distorted under the pressure of weightbearing which also causes medial or lateral deviation of the shafts of long bones. There is a decreased rate of longitudinal growth of long bones and enlargement of the ends of long bones due to the effects of weight causing flaring of the diaphysis adjacent to the epiphyseal plate. Within the thickened and widened epiphyseal plate there may be hemorrhages and minute fractures of adjacent trabecular bone of the metaphyses, and in chronic cases the hemorrhagic zone may be largely replaced by fibrous tissue. These changes can be seen radiographically as 'epiphyseal' and clinically as enlargements of the ends of long bones and costochondral junctions of the ribs. These changes at the epiphyses may result in separation of the epiphysis, which commonly affects the femoral head. The articular cartilages may remain normal or there may be subarticular collapse resulting in grooving and folding of the articular cartilage and ultimately degenerative arthropathy and osteochondrosis. Eruption of the teeth in rickets is irregular and dental attrition is rapid. Growth of the mandibles is retarded and is combined with abnormal dentition. There may be marked malocclusion of the teeth.

**Osteomalacia**

Osteomalacia is a softening of mature bone due to extensive resorption of mineral deposits in bone and failure of mineralization of newly formed matrix. There is no enlargement of the ends of long bones or distortions of long bones but spontaneous fractures of any bone subjected to weightbearing is common.

**Osteodystrophy fibrosa**

Osteodystrophy fibrosa may be superimposed on rickets or osteomalacia and occurs in secondary hyperparathyroidism.

**Diets low in calcium or that contain a relative excess of phosphorus cause secondary hyperparathyroidism.** There is extensive resorption of bone and replacement by connective tissue. The disease is best known in the horse and results in swelling of the mandibles, maxillae and frontal bones (the 'bighead' syndrome). Spontaneous fracture of long bones and ribs occurs commonly. Radiographically there is extreme porosity of the entire skeleton.

**Osteoporosis**

Osteoporosis is due to failure or inadequacy of the formation of the organic matrix of bone; the bone becomes porous, light and fragile, and fractures easily. Osteoporosis is uncommon in farm animals and is usually associated with general undernutrition rather than specifically a deficiency of calcium, phosphorus, or vitamin D. Copper deficiency in lambs may result in osteoporosis due to impaired osteoblastic activity. Chronic lead poisoning in lambs also results in osteoporosis due to deficient production of osteoid. In a series of 19 lactating or recently weaned sows with a history of lameness, weakness or paralysis, 10 had osteoporosis and pathological fractures while six had lumbar vertebral osteomyelitis. Bone ash, specific gravity of bone and the cortical to total ratio were significantly reduced in sows with osteoporosis and pathological fractures.

Ovariectomized sheep that are fed a calcium-wasting diet develop osteoporosis, which is being used as a model to study the disease in humans.

**Osteodystrophy of chronic fluorosis**

Osteodystrophy of chronic fluorosis is characterized by the development of exostoses on the shafts of long bones due to periosteal hyperostosis. The articular surfaces remain essentially normal but there is severe lameness because of the involvement of the periosteum and encroachment of the osteophytes on the tendons and ligaments.

**Congenital defects of bone**

These include complete (achondroplasia) and partial (chondrodystrophy) failure of normal development of cartilage. Growth of the cartilage is restricted and disorganized and mineralization is reduced. The affected bones fail to grow, leading to gross deformity, particularly of the bones of the head.

**CLINICAL FINDINGS**

In general terms there is weakening of the bones due to defective mineralization and osteoporosis, which results in the bending of bones, which probably causes pain and shifting lameness—one of the earliest clinical signs of acquired osteodystrophy.
The normal weight and tension stresses cause distortion of the normal axial relationships of the bones, which results in the bowing of long bones. The distortions occur most commonly in young, growing animals. The distal ends of the long bones are commonly enlarged at the level of the epiphyseal plate and circumscribed swellings of the soft tissue around the epiphyses may be prominent, and painful on palpation.

The effects of osteodystrophy on appetite and body weight will depend on the severity of the lesions and their distribution. In the early stages of rickets in calves and pigs the appetite and growth rate may not be grossly affected until the disease is advanced and causes considerable pain. Persistent recumbency due to pain will indirectly affect feed intake unless animals are hand-fed.

Spontaneous fractures occur commonly and usually in mature animals. Common sites for fractures include the long bones of the limbs, pelvic girdle, femoral head, vertebrae, ribs, and transverse processes of the vertebrae. Ordinary hand pressure or moderate restraint of animals with osteomalacia and osteo­dystrophy fibrosa is often sufficient to cause a fracture. The rib cage tends to become flattened and in the late stages affected animals have a slab-sided appearance of the thorax and abdomen. Separations of tendons from their bony insertions also occur more frequently and cause severe lameness. The osteoporotic state of the bone makes such separations easy. Any muscle group may be affected but, in young cattle in feedlots, separations of the gastrocnemius are the most common. Thickening of the bones may be detectable clinically if the deposition of osteoid or fibrous tissue is excessive, or if exostoses develop as in fluorosis. Compression of the spinal cord or spinal nerves may lead to paresthesia, paresis or paralysis, which may be localized in distribution. Details of the clinical findings in the osteodystrophies caused by nutritional deficiencies are provided in Chapter 30.

Calcification of cartilage characterized clinically by chronic wasting, lameness, ectopic calcifications of the cardiovascular system, lungs and kidneys, ulceration of joint cartilage and extensive calcification of bones.

CLINICAL PATHOLOGY
The laboratory analyses that are indicated include the following:
- Serum calcium and phosphorus
- Serum alkaline phosphatase
- Feed analysis for calcium, phosphorus, vitamin D and other minerals when indicated (such as copper, molybdenum, and fluorine)
- Bone ash chemical analysis
- Histopathology of bone biopsy
- Radiographic examination of the skeleton
- Single photon absorptiometry, a safe and noninvasive method for the measurement of bone mineral content, is now available.

Radiographic examination of the affected bones and comparative radiographs of normal bones is indicated when osteodystrophy is suspected. Radiographic examination of slab sections of bone is a sensitive method for detecting abnormalities of trabecular bone in aborted and young calves.

Serum calcium and phosphorus concentrations in nutritional osteodystrophies may remain within the normal range for long periods and not until the lesions are well advanced will abnormal levels be found. Several successive samplings may be necessary to identify an abnormal trend.

Alkaline phosphatase levels may be increased in the presence of increased bone resorption but this is not a reliable indicator of osteodystrophy. Increased serum levels of alkaline phosphatase may originate from osseous tissues, intestine or liver, but osseous tissue appears to be the major source of activity.

Nutritional history and feed analysis results will often provide the best circumstantial evidence of osteodystrophy.

The definitive diagnosis is best made by a combination of chemical analysis of bone, histopathological examination of bone and radiography. The details for each of the common osteodystrophies are discussed under the appropriate headings.

NECROPSY FINDINGS
The pathological findings vary with the cause, and the details are described under each of the osteodystrophies elsewhere in the book. In general terms, the nutritional osteodystrophies are characterized by bone deformities, bones that may be cut easily with a knife and that bend or break easily with hand pressure and the presence in prolonged cases of degenerative joint disease. In young, growing animals the ends of long bones may be enlarged and the epiphyses may be prominent and circumscribed by periosteal and fibrous tissue thickening. On longitudinal cut sections the cortices may appear thinner than normal and the trabecular bone may have been resorbed, leaving an enlarged marrow cavity. The epiphyseal plate may be increased in depth and width and appear grossly irregular, and small fractures involving the epiphyseal plate and adjacent metaphysis may be present. Separation of epiphyses is common, particularly of the femoral head. The calluses of healed fractures of long bones, ribs, vertebrae and pelvic girdle are common in pigs with osteodystrophy. On histological examination there are varying degrees of severity of rickets in young growing animals and osteomalacia in adult animals, and osteodystrophy fibrosa is possible in both young and adult animals.

TREATMENT
The common nutritional osteodystrophies due to a dietary deficiency or imbalance of calcium, phosphorus and vitamin D will usually respond favorably following the oral administration of a suitable source of calcium and phosphorus combined with parenteral injections of vitamin D. The oral administration of dicalcium phosphate, at the rate of three to four times the daily requirement, daily for 6 days followed by a reduction to the daily requirement by the 10th day, combined with one injection of vitamin D at the rate of 10 000 IU/kg BW is recommended.

DIFFERENTIAL DIAGNOSIS
In both congenital and acquired osteodystrophy the clinical findings are usually suggestive. There are varying degrees of lameness, stiff gait, long periods of recumbency and failure to perform physical work normally, progressive loss of body weight in some cases and there may be obvious contortions of long bones, ribs, head and vertebral column. The most common cause of osteodystrophy in young growing animals is a dietary deficiency or imbalance of calcium, phosphorus and vitamin D. If the details of the nutritional history are available and if a representative sample of the feed given is analyzed, a clinical diagnosis can be made on the basis of clinical findings, nutritional history and response to treatment. In some cases, osteodystrophy may be due to overfeeding, such as might occur in rapidly growing, large foals.

However, often the nutritional history may indicate that the animals have been receiving adequate quantities of calcium, phosphorus and vitamin D which necessitates that other less common causes of osteodystrophy be considered. Often the first clue is an unfavorable response to treatment with calcium, phosphorus and vitamin D. Examples include copper deficiency in cattle, leg weakness in swine of uncertain etiology — but perhaps there is weight-bearing trauma and a related lack of exercise due to confinement — or chemical poisoning such as enzootic calcification or fluorosis. These will require laboratory evaluation of serum biochemistry, radiography of affected bones and pathological examination. The presence of bony deformities at birth suggests congenital chondrodystrophy, some of which appear to be inherited while some are due to environmental influences.

HYPOCALCEMIA
OSTEOCLASTIC DISTOSIS
Although osteodystrophy and osteomalacia have been described in sheep, the condition appears to be rare and is probably related to vitamin D deficiency. These conditions are described later as bone disease and hypercalcemia, respectively.
Affected animals are placed on a diet that contains the required levels and ratios of calcium, phosphorus, and vitamin D. The oral administration of the calcium and phosphorus will result in increased absorption of the minerals, which will restore depleted skeletal reserves. Calcium absorption is increased in adult animals following a period of calcium deficiency; young animals with high growth requirements absorb and retain calcium in direct relation to intake. General supportive measures include adequate bedding for animals that are recurrent.

The treatment of the osteodystrophies due to causes other than calcium and phosphorus deficiencies depends on the cause. Copper deficiency will respond gradually to copper supplementation. There is no specific treatment for the osteodystrophy associated with leg weakness in pigs and slaughter for salvage is often necessary. Overnutrition in young, rapidly growing foals may require a marked reduction in the total amount of feed made available daily.

Oxytetracycline has been used for the treatment of flexural deformities of the distal interphalangeal joints of young foals. It is postulated that oxytetracycline chelates calcium, rendering it unavailable for use for striated muscle contraction. It is considered effective for obtaining a short-term moderate decrease in metacarpophalangeal joint angle in newborn foals. Hemicircumferential periosteal transection and elevation has gained wide acceptance for correction of angular limb deformities in young foals.

HYPERTROPHIC PULMONARY OSTEOARTHROPATHY (MARIE’S DISEASE, ACHROPHACHIA OSSEA)

Although hypertrophic pulmonary osteoarthropathy is more common in dogs than in the other domestic animals it has been observed in horses, cattle and sheep. The disease is characterized by proliferation of the periosteum leading to the formation of periosteal bone, and bilateral symmetrical enlargement of bones, usually the long bones of limbs. The enlargement is quite obvious, and in the early stages is usually painful and often accompanied by local edema. On radiographic examination there is a shaggy periostitis and evidence of periosteal exostosis. The pathogenesis is obscure but the lesion appears to be neurogenic in origin, unilateral vagotomy causing regression of the bony changes. Stiffness of gait and reluctance to move are usually present, and there may be clinical evidence of the pulmonary lesion with which the disease is almost always associated. Such lesions are usually chronic, neoplastic or suppurrative processes such as tuberculosis.

The disease is considered to be incurable, unless the thoracic lesion can be removed, and affected animals are usually euthanized. At necropsy the periostitis, exostosis and pulmonary disease are evident. There is no involvement of the joints.

OSTEOMYELITIS

ETIOLOGY AND PATHOGENESIS

Inflammation of bone is uncommon in farm animals except when infection is introduced by traumatic injury or by the hematogenous route. Bacteria can reach bone by any of three routes:

- Hematogenously
- By extension from an adjacent focus of infection
- By direct inoculation through trauma or surgery.

Focal metaphyseal osteomyelitis can occur following open fractures in the horse. Specific diseases that may be accompanied by osteomyelitis include actinomycosis of cattle and brucellosis, atrophic rhinitis and necrotic rhinitis of pigs. Nonspecific, hematogenous infection with other bacteria occurs sporadically and is often associated with omphalitis, abscesses from tail-biting in pigs or infection of castration or docking wounds in lambs. A series of 28 cases of osteomyelitis of the calcaneus of adult horses has been described.

Foals and calves under 1 month of age and growing cattle 6–12 months of age may be affected by osteomyelitis in one or more bones. The majority of foals with supplicative polyarthritis have a polyosteo-osteomyelitis of the bones adjacent to the infected joints. In a series of cases of tarsal osteomyelitis in foals there was usually evidence of infectious arthritis. Osteomyelitis of the pubic symphysis associated with Rhodococcus equi in a 2-year-old horse has been described. The lameness was localized to the pelvis and was associated with a fever and an inflammatory leukogram.

The infections occur commonly in the metaphysis, physis, and epiphysis, which are sites of bony growth and thus susceptible to blood-borne infections. The metaphyseal blood vessels loop toward the physis and ramify into sinusoids that spread throughout the metaphyseal region. Blood flow through the sinusoids is sluggish and presents an ideal environment for propagation of bacteria. Lesions occur on both sides of the physis in both the metaphysis and the epiphysis. Multiple lesions are common and support the explanation that septic emboli are released from a central focus.

In a series of 445 cattle with bone infection of the appendicular skeleton a distinction was made between hematogenous and post-traumatic origin (wound/fracture) 4. Bone infection was classified into four types according to the site of infection. Type 1 is metaphyseal and/or epiphyseal osteomyelitis close to the growth plate; type 2 is primary subchondral osteomyelitis, mostly accompanied by septic arthritis; type 3 is infectious osteoarthritis with subchondral osteomyelitis, implying that infection in the subchondral bone originates from the infection. Type 4 includes bone infections that cannot be categorized in the other groups. Hematogenous osteomyelitis was 3.2 times more frequent than post-traumatic osteomyelitis. Arcanobacteriwn (Corynebacterium) pyogenes was the most common etiological agent. About 55% of the affected animals with osseous sequestration had physical evidence of lacerations, contusions, abrasions or puncture wounds from a previous traumatic event.

Hematogenous osteomyelitis in cattle can be of:

- Physis type, in which an infection generally of metaphyseal bone originates at or near the growth plate, usually affecting the distal metacarpus, metatarsus, radius or tibia5
- Epiphyseal type, in which an infection originates near the junction of the subchondral bone and the immature epiphyseal joint cartilage, most often affecting the distal femoral condyle, the patellar and the distal radius.

The epiphyseal osteomyelitides are usually due to infection with Salmonella spp. and are most common in calves under 12 weeks of age. The physeal infections are usually due to A. pyogenes and occur most commonly in cattle over 6 months of age.

Osseous sequestration in cattle

Osseous sequestration is a common orthopedic abnormality in cattle and...
horses. In most cases, the lesions develop in the bones of the distal portion of the limbs. Sequestration is associated with trauma that results in localized cortical ischemia and bacterial invasion secondary to loss of adjacent periosteal and soft-tissue integrity and viability. The soft tissues covering the bones that comprise the distal portions of the limbs fail to provide adequate protection and collateral blood supply to the bone.

**Osteomyelitis secondary to trauma**

In horses, osteomyelitis is a frequent sequela to wounds of the metacarpal and metatarsal bones and the calcaneus. These bones have limited soft tissue covering, which may predispose them to osteomyelitis following traumatic injury. Similarly, a portion of the lateral aspect of the proximal end of the radius has limited soft-tissue covering. Penetrating and nonpenetrating wounds in this region, therefore, may result in serious consequences even though they may initially appear to be minor. Because lesions may be an extension of septic arthritis, a thorough examination of the wound area is necessary.

Osteomyelitis of the sustentaculum tali in horses has been described. Osteomyelitis of the cervical vertebrae, usually the fourth to sixth vertebrae, causing a typical syndrome of abnormal posture and difficulty with ambulation. Initially there is a stumbling gait, which then becomes stiff and restricted and with a reluctance to bend the neck. Soon the animal has difficulty eating off the ground and must kneel to graze pasture. At this stage there is obvious atrophy of the cervical muscles and pain can be elicited by deep, forceful compression of the vertebrae with the fists. There is no response to treatment and at necropsy there is irreparable osteomyelitis of the vertebral body and compression of the cervical spinal cord. Radiological examination is usually confirmatory.

Cervicothoracic vertebral osteomyelitis in calves between 2 and 9 weeks of age is characterized by difficulty in rising with a tendency to knuckle or kneel on the forelimbs, which are hypotonic and hyporeflexic. Pain can be elicited on manipulation of the neck. The lesion usually involves one or more of the vertebrae from C6-T1. *Salmonella dublin* is commonly isolated from the vertebral lesion.

**Clinical Findings**

The common clinical findings of osteomyelitis include:
- Lameness
- Generalized soft tissue swelling and inflammation
- Pain on palpation of the affected area
- Chronic persistent drainage
- Secondary muscle atrophy of the affected limb

Erosion of bone occurs and pus discharges into surrounding tissues, causing a cellulitis or phlegmon, and to the exterior through sinuses, which persist for long periods. The affected bone is often swollen and may fracture easily because of weakening of its structure. When the bones of the jaw are involved, the teeth are often shed and this, together with pain and the distortion of the jaw, interferes with mastication and mastication. Involvement of vertebral bodies may lead to the secondary involvement of the meninges and the development of paralysis. Lameness and local swelling are the major manifestations of involvement of the limb bones.

Most osseous sequestra in cattle are associated with the bones of the extremities, most commonly the third metacarpal or metatarsal bone. Cattle 6 months to 2 years of age are most likely to have a sequestrum compared with animals less than 6 months of age. The lesions are typically destructive of bone and cause severe pain and lameness. Those associated with *Salmonella* spp. are characteristic radiographically in foals and calves. *A. pyogenes*, *Corynebacterium* spp., and *E. coli* may also be causative agents. Affected animals are very lame and the origin of the lameness may not be obvious. A painful, discrete soft-tissue swelling over the ends of the long bones is often the first indication. The lameness characteristically persists in spite of medical therapy and the animal may become lame in two or more limbs and spend long periods recumbent.

Osteomyelitis affecting the cervical vertebrae, usually the fourth to sixth vertebrae, causing a typical syndrome of abnormal posture and difficulty with ambulation. Initially there is a stumbling gait, which then becomes stiff and restricted and with a reluctance to bend the neck. Soon the animal has difficulty eating off the ground and must kneel to graze pasture. At this stage there is obvious atrophy of the cervical muscles and pain can be elicited by deep, forceful compression of the vertebrae with the fists. There is no response to treatment and at necropsy there is irreparable osteomyelitis of the vertebral body and compression of the cervical spinal cord. Radiological examination is usually confirmatory.

**Clinical Pathology**

Radiographic changes include:
- Necrotic sequestrum initially
- New bone formation
- Loss of bone density.

The lesions are characteristically centered at the growth and extend into both metaphysis and epiphysis. Culture of the inflammatory exudate and necrotic sequestra removed surgically is necessary to determine the species of bacteria and their antimicrobial sensitivity. Samples of bone obtained at surgery provide the most accurate culture results compared to specimens obtained from the draining sinuses, which may yield a mixed flora. Specimens should consist of sequestra and soft tissues immediately adjacent to bone thought to be infected. Special transport media are desirable for optimum culture results. Anaerobic bacteria are frequently associated with osteomyelitis and should be considered when submitting samples for culture.

**Necropsy Findings**

At necropsy the osteomyelitis may not be obvious unless the bones are opened longitudinally and the cut surfaces of the metaphysis and epiphysis are examined.

**Differential Diagnosis**

A differential diagnosis for a destructive lesion in the end of a long bone of a foal or calf would include: a healing fracture, traumatic periostitis or osteitis, bone tumor, nutritional osteodystrophy and infection of the bone due to external trauma, fracture, extension from adjacent infection or hematogenous spread. The absence of equal pathological involvement in the comparable parts of long bones and the young age of the animal will usually suggest infection of bone. The pathological features of multiple bone infection in foals are described.

**Treatment**

Despite advances in antimicrobial therapy and refined diagnostic techniques, the clinical management of osteomyelitis is difficult. Medical therapy alone is rarely completely successful because of the poor vascularity of the affected solid bone and the inaccessibility of the infection. In cases of long-term infection or those with extensive bone necrosis, surgery is generally recommended to remove sequestra, devitalized tissue and sinus tracts that are harboring large numbers of bacteria. Good results are obtained when the affected bone is removed and the affected area is irrigated daily through a temporary drainage tube.

In septic physisis, the implantation of homologous cancellous bone grafts following debridement of necrotic bone, and the application of a walking cast for 4–5 weeks and antimicrobial therapy for 2 weeks was highly successful. Absolute asepsis is required for successful application of a bone graft and, after
debridement of the necrotic bone, the cavity is flushed with saline and ampicillin.

Antimicrobials are an integral part of the treatment and selection of the most appropriate drug should be based on identification of the organism. Parenteral antimicrobial therapy should be continued for 4-6 weeks following surgical curettage. However, in a series of osteomyelitis of the calcaneus of adult horses, there was no difference in the survival rate of animals between those treated surgically and those treated conservatively. Prolonged antibiotic therapy can be successful for the treatment of osteomyelitis of the proximal end of the radius in the horse.

Most anaerobic bacteria associated with osteomyelitis are sensitive to penicillin and the cephalosporins, but some species of *Bacteroides fragilis* and *Bacteroides asaccharolyticus* and other species of *Bacteroides* are known to produce beta-lactamases, which can inactivate penicillin and cephaporphin. Metronidazole and clindamycin will penetrate bone and can be considered.

**ARTHROPATHY (OSTEOARTHROPATHY, DEGENERATIVE JOINT DISEASE)**

The terms osteoarthropathy and degenerative joint disease are used here to describe noninflammatory lesions of the articular surfaces of joints characterized by:

- Degeneration and erosion of articular cartilage
- Eburnation of subchondral bones
- Hypertrophy of bone surrounding the articular cartilage resulting in lipping and spur formation at the joint margins.

Osteochondrosis is a degeneration of both the deep layers of the articular cartilage and the epiphyseal plate - a defect in endochondral ossification - which occurs in pigs and horses and is similar to the well-recognized disease in dogs.

**ETIOLOGY AND EPIDEMIOLOGY**

The etiology is not clear but in most of the commonly occurring cases the lesions are considered to be multifactorial and perhaps secondary to conformational defects resulting in excessive joint laxity, acute traumatic injury of a joint, the normal aging process and nutritional deficiencies. The etiological information is primarily circumstantial and some of the epidemiological observations that have been associated with osteoarthropathy of farm animals are outlined here.

**Nutritional causes**

- Secondary to, or associated with, rickets, osteomalacia, bowie and osteodystrophia fibrosa
- Coxofemoral arthropathy in dairy cattle associated with aphasisporosis
- Copper deficiency thought to be related to enlargement of limb joints in foals on pasture and pigs fed experimental copper-deficient diets
- Experimental diets deficient in manganese or magnesium causing arthropathy and joint deformity in some calves
- Experimental riboflavin deficiency in pigs.

**Poisonings**

- Chronic zinc poisoning in pigs and foals
- Fluorosis in cattle
- As part of the enzootic calcinosis syndrome caused by poisoning with *Solamum malacoxylon* and others.

**Steroid-induced**

The intra-articular injection or prolonged parenteral administration of corticosteroids in horses may lead to degenerative joint disease.

**Biomechanical trauma**

- Acute traumatic injury, e.g. injury to joint surfaces, menisci and ligaments, especially the cruciate ligaments of the stifle joints of breeding bulls, may lead to chronic progressive osteoarthritis. Injuries to the femoral ligaments of horses can predispose to osteoarthropathy of the stifle joint
- Repeated subacutec trauma to joint surfaces can lead to degenerative arthropathy. This is common in young racehorses in training, which may have their joint surfaces and surrounding tissues made susceptible to injury because of conformational defects and subtle deficiencies of calcium and phosphorus. Hard running surfaces may also contribute to the onset
- Trauma caused by movement is suspected of contributing to the erosive lesions on the articular surfaces of some horses affected by enzootic incoordination, the intervertebral joints of caudal thoracic and cranial lumbar vertebrae of old bulls with spondylitis, and the condition of bulls with inherited spasticity. Coxofemoral osteoarthropathy may occur in aged horses with joint instability and in calves with hip dysplasia.

**Growth rate, body size, and genetic predisposition**

Degenerative coxofemoral arthropathy occurs in young beef bulls as early as 9 months of age. A congenital shallow acetabulum may predispose. It may be secondary to hip dysplasia, but in some cases there is no evidence of this. The large, weightbearing joints subjected to the greatest movement and concussion appear to be most susceptible. Rapidly growing bull calves appear to be most susceptible and some of them have an inherited susceptibility.

**Osteochondrosis**

Osteochondrosis is an important cause of lameness in horses. It is usually seen in young, rapidly growing animals, and affects males more commonly than females. The predilection sites of osteochondrosis in the horse and their general order of incidence are hock, stifle, shoulder, fetlock, and cervical spine. The stifle, hock, and shoulder joints are more commonly affected, but many other joints may also be affected, including the metatarsal and metacarpal bones and rarely the acetabulum of young foals.

The epidemiology, heritability and body measurements and clinical findings of osteochondrosis of hock and fetlock joints in Standardbred trotters have been examined. The incidence of the disease is high in the Swedish Standardbred population and well developed by the age of 1.5 years. The incidence of osteochondrosis is higher in horses born later in the foaling season than earlier and the incidence was related to body size: affected horses were taller at the withers and had a greater circumference of the carpus. This suggests that differences in body size at birth and the first few months of the foal’s life are of major importance in the development of osteochondrosis. The heritability estimates of osteochondrosis in the hock and fetlock joints of 753 Standardbred trotters 6-21 months of age was 0.52 and 0.21, respectively.

**Aging process**

Degenerative arthropathy in aged dairy cows and bulls may be a manifestation of the normal aging process. Osteochondrosis, degenerative joint disease and vertebral osteophysis occur in middle-aged bulls.
Osteoarthrosis of the antebrachial joint of riding horses has been described. Affected animals were aged mares that developed osteoarthrosis and ankylosis. The cause was unknown.

**Conformation and intensive animal production**

Osteoarthropathy occurs in rapidly growing cattle and pigs raised in confinement on hard, usually concrete, floors and with minimal exercise. Osteochondrosis in feedlot cattle may be associated with a high-caloric diet and rapid growth rate. It is thought that weight-bearing trauma in these rapidly growing animals is sufficient to cause degenerative lesions of certain joints, especially in animals with a skeletal conformation that results in abnormal stress on certain weightbearing condyles of long bones.

In a series of 42 cases of stifle lameness in cattle, 18 had evidence of subchondral bone cyst and ranged in age from 6–18 months. It is suggested that the subchondral bone cyst is an indicator of osteochondrosis. In a series of osteochondrosis in cattle, male, purebred cattle of a mean age of 21 months were affected. Osteochondrosis may occur in rapidly growing bull beef calves fed a diet lacking adequate calcium, sodium, copper and vitamins A, D, and E. Grazing beef cattle on improved native pasture in which a common ancestral sire and gender (all males) may have been contributing factors. Severe osteochondrosis of multiple joints but with remarkable changes in the humeral head and glenoid of both shoulder joints in 10-month-old beef calves has been described.

Osteochondrosis similar to that seen in pigs has been recorded in purebred Suffolk lambs raised in a system designed to produce rapidly growing, high-value rams. The disease has been recorded in a single pedigree Suffolk ram.

**Osteochondrosis and arthrosis** are considered to be major causes of ‘leg weakness’ in rapidly growing pigs. Restricting the energy intake appears to decrease the prevalence and severity of osteochondrosis when gilts are examined at 100 kg. The prevalence and severity of osteochondrosis in growing pigs is probably not related to floor type. Recent work has shown a significant relationship between body conformation and the presence of joint lesions. Pigs with a narrow lumbar region, broad hams and a large relative width between the stifle joints were highly susceptible to poor locomotor ability due to lesions in the elbow and stifle joints, the lumbar intervertebral joints and the hip joint.

This excellent work represents real progress in understanding the relationship between skeletal conformation and bone and joint lesions. It is postulated that inherited weakness of muscle, ligaments, cartilage and anterior joint conformation results in local overloading in the joint and the development of osteochondrosis and arthrosis. Some breeds, such as the Duroc, have more problems of structure and movement in the front legs than in the rear legs, but osteochondrosis is not responsible for the leg weakness. Osteochondrosis has been recorded in wild boar–Swedish Yorkshire crossbred pigs in which the growth rate was low.

**Osteoarthrosis of the distal tarsal joints of the horse (bone spavin)**

Osteoarthrosis of the distal tarsal joints (hock), commonly known as bone spavin, is common in Icelandic horses and strongly related to age. In Icelandic horses aged 6–12 years and used for riding, the prevalence of radiographic signs of osteoarthrosis in the distal tarsus increased from 18% in horses 6 years of age to 54% in 12-year-old horses. The age onset of radiographic signs reflect a predisposition to bone spavin indicating a trait with medium–high heritability. There is a high prevalence of chondro-necrosis in young Icelandic horses, indicating an early onset and slow progression of disease. The disease is the most common cause of culling due to disease in riding horses in the age group 7–17 years.

**PATHOGENESIS**

The details of the pathogenesis of degenerative joint disease have been reviewed. A brief review of the structure and biochemistry of the normal articular joint will serve as background for understanding the pathogenesis of osteoarthropathy. Articular cartilage is a tissue consisting of chondrocytes scattered in a matrix of collagen fibers and an amorphous intercellular substance containing proteoglycans. Articular cartilage contains no nerves, is avascular and has a high matrix-to-cell ratio. The chondrocytes are the only living matter in cartilage, produce the fine strands of collagen and are engaged in protein and proteoglycan synthesis. The matrix of the cartilage consists of water-soluble proteoglycans interspersed with collagen fibers, which are arranged in parallel rows superficially and crisscross rows closer to the calcified layer. This enables the cartilage to withstand shearing stresses superficially and compression more deeply.

The proteoglycans are glycosaminoglycan–protein complexes, bound by a link glycoprotein to a linear hyaluronic acid molecule. The glycosaminoglycans in articular cartilage are chondroitin 4-sulfate, chondroitin 6-sulfate and keratan sulfate. About 75% of the proteoglycans exist on aggregates that protect them from degradation and, because of their high water content, form large polyanionic complexes that have considerable elastic resistance to compression.

Nutrition of the articular cartilage is provided via the synovial fluid and is dependent on the capillary flow to the synovial membrane. Nutrients flow through the synovial fluid and diffuse through the cartilage to the chondrocytes. Proteoglycans are synthesized by the chondrocytes and secreted to the cell exterior. Proteoglycans are also degraded intracellularly by lysosomes. The normal equilibrium between anabolism and catabolism is maintained by several different low-molecular-weight proteins. When the equilibrium is disturbed and shifts toward catabolism, degeneration occurs.

**Primary osteoarthropathy**

This is due to normal aging processes and ordinary joint usage. The initial lesions occur in the superficial layers of the articular cartilages where, with increasing age, there is loss of the normal resilience of the cartilage, a lowering of the chondroitin sulfate content and reduction in the permeability of the cartilaginous matrix, which results in progressive degeneration of the articular cartilage. There is growth of the articular cartilage, ebullition of subchondral bone and secondary hypertrophy of marginal cartilage and bone, with the formation of pear-like osteophytes. In experimentally induced arthritides in the horse the major changes include synovitis, increased synovial effusion and superficial fibrillation with chondrocyte necrosis in the articular cartilage. These are comparable to the early changes in naturally occurring degenerative joint disease.

**Secondary osteoarthropathy**

This appears to be initiated by injuries or congenital conformational defects that create greater shearing stresses on particular points, in contrast to the intermittent compressive stresses typical of ordinary weightbearing. These irregular stresses result in cartilaginous erosion, increased density of subchondral bone at points of physical stress and proliferation of bone and cartilage at the articular margins.

**Following acute trauma**, the initial changes are often characterized by acute synovitis and capsulitis. As a result of the inflammatory response, leukocytes, prostaglandins, lysosomal enzymes and hyaluronidase enter the synovial fluid, which becomes less viscous and affects the nutrition of the cartilage. There is
some evidence of immune complexes associated with collagen-type-specific antibodies in horses with secondary osteoarthritis. Cytokines can be detected in the synovial fluid after racing in horses with degenerative joint disease. The cartilage matrix undergoes a variety of changes, possibly because of chondrocyte damage with lysosomal enzyme release, or to collagen fiber injury. There is an increase in water content and loss of orientation of the collagen fibers. Proteoglycans are lost and, while increased chondrocyte activity synthesizes proteoglycans, they are of lower molecular weight and altered glycosaminoglycan composition. This leads to loss of elasticity and surface integrity of the cartilage, resulting in increased friction, blistering and ulceration. There is additional lysosomal enzyme release from the chondrocytes, resulting in matrix destruction and further proteoglycan destruction. The degrading enzymes enter the altered matrix and cause further degradation.

The first stage of matrix degradation involves discolarization, softening and blistering of the tangential layer of the cartilage surface, a process known as early fibrillation. As the fissuring extends to the radial layer, microfractures occur, with loss of cartilage fragments (detritus) into the synovial fluid. As the cartilage is destroyed the underlying bone is exposed and becomes sclerotic. Bone proliferation occurs in the floor of the cartilage lesions, while at the joint margins osteophyte formation occurs. The pathogenesis of degenerative joint disease indicates that the ideal treatment would be the use of a substance that would promote synthesis of matrix components and retard catabolic processes.

The major proteoglycan in cartilage is a high-molecular-weight aggregate that contains chondroitin sulfate and keratin sulfate chains located on specific regions of the core protein. These macromolecules are continuously released into the synovial fluid during normal cartilage matrix metabolism. Cartilage proteoglycans are degraded early in the course of joint disease and released from the cartilage into the synovial fluid, where they can be identified.

In horses with degenerative joint disease, proteoglycan fragments – glycosaminoglycans – have been determined in equine synovial fluid as indicators of cartilage metabolism in various types of arthropathies. The presence of high-molecular-weight proteoglycans and high concentrations of hyaluronate in horses with various arthropathies – acute or chronic traumatic arthritis, intra-articular fracture and infectious arthritis, with and without abnormal radiographic and/or arthroscopic findings – compared with control joints has been investigated. The intra-articular injection of corticosteroids depresses chondrocyte metabolism, alters the biochemical composition and causes morphological changes in the articular cartilage, which remains biochemically and metabolically impaired for several or more weeks.

In femoral–tibial osteoarthritis of bulls the secondary degenerative joint lesions are due to rupture of the attachments of the lateral meniscus resulting in mechanical instability in the joint with unusual mechanical stresses on the articular cartilage leading to degeneration. The cranial cruciate ligament becomes progressively worn and eventually ruptures, resulting in loss of all joint stability and the development of gross arthrosis. In cattle with severe degenerative joint disease of the coxofemoral joints, an acetabular osseous bula may develop at the cranial margin of the obturator foramen.

Osteochondrosis

Osteochondrosis (dyshondroplasia) is characterized by disturbance of the normal differentiation of the cells in the growing cartilage. Both the metaphyseal growth plate (the growth zone of the diaphysis) and immature joint cartilage (the growth zone of the epiphysis) are affected. The loss of normal differentiation of the cartilage cells results in failure of provisional calcification of the matrix and endochondral ossification ceases. Degeneration and necrosis of blood vessels in cartilage canals results in ischemia of an area of growing cartilage followed by chondrocyte degeneration and death. The initial lesion occurs in growing cartilage and dyschondroplasia is a more appropriate term. The primary lesion of osteochondrosis directly affects the differentiation and maturation of the cartilage cells and the surrounding matrix that are destined to become replaced by bone. This can occur at the two sites of endochondral ossification in long bones – the articular/epiphyseal cartilage complex and the metaphyseal growth plate. In osteochondrosis, the capillary buds fail to penetrate the distal region of the hypertrophic zone, which leads to a failure of the final stages of cartilage maturation and modification of the surrounding matrix. These changes lead to retention and thickening of cartilage with subsequent weakening of the articular/epiphyseal cartilage complex.

Typical lesions in the horse involve extensive cartilaginous and subchondral bone degeneration with flap formation and, ultimately, loose pieces in the joint. This is usually referred to as osteochondritis dissecans and is associated with synovial effusion and varying degrees of synovitis. Osteochondral fracture associated with severe pathological changes to the subchondral bone occurs most commonly on the trochlear ridges and the lateral or medial malleoli of the hock. In some instances, cartilage damage weakens underlying bone and causes a bone cyst to form, usually at a site of biomechanical stress or weightbearing.

It is suggested that osteochondrosis lesions in horses develop prior to 7 months of age and that ischemic necrosis of cartilage secondary to a defect in vascular supply is an important factor in the pathogenesis of the disease in horses. An osteochondrotic lesion in the metaphyseal growth plate may disturb growth to such a degree that the whole shape of the bone is altered. Ephysyolysis may also occur. Osteochondrosis of joint cartilage may lead to osteochondritis dissecans and secondary osteoarthritis. The lesion may heal and only the sequelae are present once the period of growth is over.

In rapidly growing pigs raised in confinement with minimal exercise, osteochondrosis and arthrosis are seen as degeneration of the deep layer of the articular cartilage and adjacent subchondral bone with degenerative lesions of the epiphyseal plate. Lesions in the epiphyseal plate may result in ephysysis, which occurs most commonly in the femoral head. The typical lesions are usually symmetrical and commonly involve the elbow, stifle and hip joints and the distal epiphyseal plate of the ulna. Lesions also occur in the intervertebral articulations. The lesions are common in pigs when they are examined at slaughter (90–100 kg BW) and there may have been no evidence of clinical abnormality or a proportion of the pigs with severe lesions may have been affected with the leg-weakness syndrome. Osteochondrosis and Erysipelothrix rhusiopathiae are the most common causes of nonsuppurative joint disease of pigs examined at the abattoir. Thus not all lesions are clinical.

CLINICAL FINDINGS

The major clinical characteristic is a chronic lameness that becomes progressively worse over a long period of time and does not usually respond to treatment. The disease is insidious and generally not clinically apparent in the early stages. A common clinical history is that the affected animal becomes progressively more lame over a period of weeks and months and prefers long periods of recumbency. The lesion may develop slowly over a period of weeks and months during the convalescent
stages of an acute traumatic injury to the joint when recovery is expected but the animal continues to be lame. Young breeding bulls in the early stages of coxofemoral arthropathy may be reluctant to perform the breeding act and yet appear to have sufficient libido. One of the first clinical abnormalities of osteochondrosis and epiphyseolysis in young breeding boars may be in ability to mount the sow – impotence coeundi.

There is usually difficulty in flexing affected joints normally, which results in a stiff and stilted gait. In cattle confined to stanchions one of the earliest and persistent signs is shifting of weight from limb to limb. In dairy cattle, as the lesions become more painful, there is a decline in appetite and milk production, prolonged recumbency and considerable difficulty in rising from the recumbent state. In the early stages there may be an apparent remission of the lameness, but relapses are common. The bony prominences of the joint eventually appear more prominent than normal, which is due to disuse muscle atrophy of the affected limbs. Distension of the joint capsule is not a characteristic, as it is in an infectious or suppurative arthritis. The joint capsule of palpable joints is usually not painful on palpation. Passive flexion of affected joints may be painful and it may be possible to elicit crepitus due to detached pieces of cartilage and bone and osteophytes surrounding the articular cartilage. However, crepitus is most common in the large movable joints, such as the stifle, and commonly in osteoarthropathy secondary to acute traumatic injury of the meniscus and cranial cruciate ligament of the joint.

Epiphyseolysis of the head of the femur occurs in young pigs from 5 months to 1 year of age. There is usually a history of slight to moderate lameness, sudden in onset and affecting one or both hindlimbs. The onset of lameness may coincide with some physical activity such as breeding, farrowing or transportation. The lameness is progressive and in about 7–10 days the animal is unable to use its hindlegs. Crepitus may be audible on circumduction of the affected limb and radiography may reveal the separation.

In leg weakness associated with osteochondrosis and arthrosis of pigs the common clinical findings are hyperflexion of the carpus, limb bowing, adduction of both forelegs at the level of the carpus, hyperextension of the fore and hind phalanges and anterior curvature of the tarsus. Locomotory dysfunction involves primarily the hindlegs. There is pronounced swaying of the hindquarters, and crossing the hindlegs with each step, which makes the pig appear incoordinated.

Osteochondrosis in cattle is characterized by chronic long-standing lameness, either with or without joint effusion. Joint fluid analysis is usually normal or indicates nonseptic inflammation. The stifle joint is most commonly affected followed by the hock joint. In osteochondrosis in young growing bulls there is reluctance to move, stiffness, enlargement of the ends of long bones and a straightened joint. While there may be clinical evidence of lameness in less than 40% of affected cattle, radiographically, 88% of the lesions are bilateral.

Osteochondrosis in the horse is characterized by a wide range of clinical signs and in some cases lesions are not accompanied by clinical signs. The most common sign of osteochondrosis is a nonpainful distension of an affected joint. In foals under 6 months of age, a tendency to spend more time lying down is common. This is accompanied by joint swelling, stiffness and difficulty keeping up with the other animals in the group. An upright conformation of the limbs may also be present. In yearlings or older animals the common clinical signs are stiffness of joints, flexion responses and varying degrees of lameness.

In the horse with osteochondrosis of the shoulder joint there is intermittent lameness, characterized by a swaying leg, shoulder lameness with pain elicited by extension, flexion or abduction of the limb. Secondary joint disease is also a common finding. In a retrospective study of osteochondrosis dissecans in 21 horses, affected animals were 8 months to 5 years of age. The usual age of onset of clinical abnormalities was 18–24 months. The common presenting complaints included joint effusion and lameness of either gradual or sudden onset. The prevalence was higher in males than in females.

CLINICAL PATHOLOGY

Joint fluid
The changes in the synovial fluid of joints affected with degenerative arthropathy are usually unremarkable and can be distinguished from the changes in infectious arthritis. A summary of the laboratory evaluation of synovial fluid in diseases of the joints is set out in Table 13.2. The isolation of an infectious agent from the synovial fluid of a diseased joint suggests the presence of an infectious arthritis but failure to isolate an organism must not be interpreted as the presence of a noninfectious arthritis. In well advanced cases of infectious arthritis the number of organisms may be small or they have been phagocyted by neutrophils in the joint fluid.

Total protein concentration and viscosity of synovial fluid of horses can be determined. Normal values are available and the concentration and molecular weight distribution of hyaluronate in synovial fluid from clinically normal horses and horses with diseased joints have been compared. Synovial fluid viscosity is reduced in horses with infectious and chronic arthritides and with radiographic evidence of cartilage degeneration. The synovial fluid hyaluronate concentration can be used as a diagnostic marker for chronic traumatic arthritis. However, high-molecular-weight proteoglycans or other markers in the synovial fluid cannot be used for diagnosing or monitoring degenerative joint disease.

Hematology and serum biochemistry should be combined with appropriate hematology and serum biochemistry where indicated. The concentration of hyaluronic acid in synovial fluid can be determined using an assay technique. The determination of serum calcium and phosphorus may reveal the existence of a dietary deficiency or imbalance of minerals.

Radiography
Radiography of the hock joints in a cranio-medial–caudalateral oblique view and of the fetlock joints in lateromedial view are standard techniques for the diagnosis of osteochondrosis in the horse. Those joints with abnormal radiographs may be radiographed from additional perspectives. Horses with bony fragments or defects at the cranial edge of the intermediate ridge of the distal aspect of the tibia or defects at the lateral trochlea of the talus can be classified as having osteochondrosis. The radiographic progression of femoropatellar osteochondrosis in horses under 1 year of age at the onset of clinical signs has been examined. The full extent of the radiographic lesions may take several weeks to develop.

Arthroscopy
Arthroscopic examination and surgery of affected joints of horses with osteochondrosis can provide considerably more information than is possible from clinical and radiographic examination alone.

NECROPSY FINDINGS

In degenerative joint disease the joint cartilage is thin or patchily absent and polished subchondral bone is evident. The articular surfaces are irregular and sometimes folded. Exposed bone may be extensively eroded and osteophytes (small bone excrescences, like pearls) may be present on the nonarticular parts of the joint on the circumference of the articular cartilage. The synovial fluid is usually only slightly increased in volume and appears
The pathology of coxofemoral arthropathy in young bulls is described. The head of the femur becomes smaller and more flattened than naturally occurring degenerative joint disease in large animals, radiographic changes may not be visible and repeated examinations may be necessary. The radiographic changes of equine osteochondrosis in the shoulder joint of the horse consist of:

- Alteration in the contour of the humeral head and glenoid cavity
- Periarticular osteophyte formation
- Sclerosis of the subchondral bone
- Bone cyst formation

The pathology of coxofemoral arthropathy in the horse is similar to the early changes of naturally occurring degenerative joint disease.

In osteochondrosis there is splitting and invagination of articular cartilage, loss of articular cartilage, chip fractures of condyles, exposed and collapsed subchondral bone, osteophyte formation around the circumference of the articular cartilage and loose pieces of cartilage in the joint. In the epiphyseal plates (e.g., the distal ulna in pigs with leg weakness) the cartilage is uneven and thickened with hemorrhage, fibrous tissue, collapse of bone tissue in the metaphysis and epiphyseal separation. Complete separation of the epiphysis occurs most commonly at the head of the femur. The ultrastructural appearance of normal epiphyseal cartilage of the articular–epiphyseal cartilage complex in growing swine has been examined and serves as a standard for comparison with the lesions in affected pigs. The lesions may be present in pigs at an early age as part of the usual growth pattern of cartilages.

**In equine osteochondrosis (dyschondroplasia), the histological lesions can be divided into two groups.**

In one group there are accumulations of small rounded chondrocytes, areas of necrosis and chondrocyte clusters. In the second group, there are alterations in the appearance of the mineralized matrix, areas of necrosis, chondrocyte clusters and an alteration in type VI collagen immunoreactivity within the chondrocyte clusters.

**TREATMENT**

The treatment of arthropathy depends largely upon correction of the cause, but in most cases the lesions are progressive and irreparable and food-producing animals should be slaughtered for salvage. Tarsal degenerative joint disease in cattle has been treated with intra-articular injections of corticosteroids and has provided temporary relief from pain and discomfort. However, the corticosteroids do not promote healing of the joint and their use in arthropathy may actually accelerate erosion of articular cartilage, loss of joint sensation and the development of 'steroid arthropathy'. Large doses of acetylsalicylic acid may be given to reduce pain in animals that are kept for breeding purposes.

### Differential Diagnosis

Osteoarthritis is characterized clinically by a chronic lameness that becomes progressively worse and usually does not respond to treatment. The gait is stiff, there is disuse muscle atrophy, the bony prominences of the joint are more apparent but usually there is no marked distension and pain of the joint capsule, as in infectious arthritis. Examination of synovial fluid may aid in differentiation from infectious arthritis.

Radiographically there is erosion of articular cartilage, sclerosis of subchondral bone and periarticular accumulations of osteophytes. In the early stages of the disease in large animals, radiographic changes may not be visible and repeated examinations may be necessary. The radiographic changes of osteoarthritis in the shoulder joint of the horse consist of:

- Alteration in the contour of the humeral head and glenoid cavity
- Periarticular osteophyte formation
- Sclerosis of the subchondral bone
- Bone cyst formation

Other laboratory analyses of synovial fluid include: sugar content, alkaline phosphatase activity, lactic dehydrogenase activity, aldolase activity, glutamic oxaloacetic transaminase activity, glutamic pyruvic transaminase activity, mucinous precipitate quality.

**Nonsteroidal anti-inflammatory agents**

Several nonsteroidal anti-inflammatory drugs (NSAIDs), such as phenylbutazone, flunixin meglumine, ketoprofen, naproxen, and carprofen, are available treatment options. Each has associated toxicities. They are now the most commonly used drugs because of their analgesic, antipyretic and anti-inflammatory properties. They inhibit some component of the enzyme system that converts arachidonic acid into prostaglandins and thromboxanes. All cells, including chondrocytes and synoviocytes, possess arachidonic acid as a fatty acid constituent of phospholipids. Once released, arachidonic acid is oxidized by either cyclooxygenase (COX) or 5-lipoxygenase. COX oxidation leads to prostaglandin production, while lipoxygenase oxidation leads to leukotriene formation. The effect of NSAIDs is primarily from inhibiting COX, which blocks arachidonic acid conversion to prostaglandin.

**Intra-articular steroids**

Various steroid formulations for intra-articular administration are available and correct dosage, frequency of administration, indications and toxicity are factors to consider for each drug. They include methylprednisolone acetate, betamethasone, and triamcinolone acetone.
Chondroprotective agents

Various chondroprotective drugs such as hyaluronic acid, polysulfated glycosaminoglycan, and oral glucosamine-chondroitin sulphate are also used to control inflammation and provide viscosupplementation.25

There is a notable lack of treatment information based on randomized, blinded placebo-controlled clinical trials in the horse to identify the efficacy of therapeutic agents for both symptomatic and disease-modifying activity in degenerative joint disease.25 Until there are validated outcome measures that can be used practically in clinical trials, there will always be uncertainty about whether these therapeutic agents have any real disease-modifying action.26

Hyaluronic acid

The changes in the synovia following the intra-articular injection of sodium hyaluronate into normal equine joints and after arthroscopy and experimental cartilage damage have been examined, but in general the results are inconclusive.

Polysulfated glycosaminoglycans

Polysulfated glycosaminoglycans have been reported to induce arthritic cartilage matrix synthesis and to decrease matrix degradation,27 Experimentally, intra-articular injections of polysulfated glycosaminoglycan provides some protection against chemically induced articular cartilage damage but not against physical defects of articular cartilage in the horse. The polysulfated glycosaminoglycans inhibit lysosomal enzymes and neutral proteases. The allo-transplantation of synovial fluid into the joints of horses with arthropathies has been examined. A survey of the use of polysulfated glycosaminoglycans by equine practitioners for the treatment of lameness in horses found that the drug is moderately effective overall and is considered most beneficial in the treatment of subacute degenerative joint disease.28 Its efficacy for incipient and chronic forms of degenerative joint disease is considered comparable to that of sodium hyaluronate.

The prevention of further trauma should be assured and possible nutritional causes corrected. The treatment of active disease, particularly in soft tissues, that is contributing to articular degeneration includes rest, immobilization, physical therapy, intra-articular injections of corticosteroids, NSAIDs, joint lavage and intra-articular injection of sodium hyaluronate, all of which have been used with variable success.29

Other treatments

Surgical therapy includes curettage of articular cartilage, removal of osteophytes and surgical arthrodesis.29 In a retrospective study of stifles lameness in 42 cattle admitted to two veterinary teaching hospitals over a period of 6 years, 18 had radiographic evidence of subchondral bone cyst without radiographic evidence of degenerative joint disease. The prognosis in those with a subchondral bone cyst was favorable, 75% returning to their intended function, while in septic arthritis only 22% returned to normal.

Chemical arthrodesis using the intra-articular injections of monooiodoacetate (MIA) has been described as an alternative to surgical arthrodesis for the treatment of degenerative joint disease of the distal tarsal joints.28 MIA causes an increase in intracellular concentration of adenosine triphosphate resulting in inhibition of glycolysis and cell deaths. It causes dose-dependent cartilage degeneration characterized by cartilage fibrillations, chondrocyte death and glycosaminoglycan and proteoglycan depletion. MIA produces reliable radiographic and histological changes of the distal tarsal joints. Resolution of the lameness required 12 months and occasionally longer. Soundness was achieved in 82% and 85% of horses at 12 and 24 months, respectively. Complications of the injections were uncommon and were probably related to peri-articular injection or leakage of MIA, or to use of higher concentrations or volumes. Postinjection pain was marked in a small number of horses but was transient and managed effectively with analgesics. The procedure is controversial.31 Some clinicians argue that arthrodesis should only be used where lameness is localized to the tarsometatarsal and centrodial joints with objective means such as local analgesic techniques, and when other more conservative treatments have failed.

CONTROL AND PREVENTION

Prevention of osteoarthropathy will depend upon recognition and elimination of the predisposing causes: provision of an adequate diet and the avoidance of overnutrition; regular exercise for confined animals; the provision of suitable flooring to minimize persistent concussion and the use of breeding stock that have a body conformation that does not predispose to joint lesions.

REVIEW LITERATURE

REFERENCES

ARTHRITIS AND SYNOVITIS

Inflammation of the synovial membrane and articular surfaces as a result of infection occurs commonly in farm animals. It is characterized by varying degrees of lameness and a warm and swollen painful joint. The synovial fluid is usually abnormal, containing an increased leukocyte count and the pathogens causing the arthritis. The arthritis may be severe enough to cause systemic illness, and in some cases a draining sinus tract may occur.

ETIOLOGY AND EPIDEMIOLOGY

Specific bacterial infections in the joints are most common in newborn farm animals, in which localization of infection occurs in joints following bacteremia or septicemia. Surveys of Thoroughbred studs have shown that the incidence of infectious arthritis is higher in foals with other perinatal abnormalities and in which the ingestion of colostrum was delayed for more than 4 hours after birth. Calves with hypogammaglobulinemia are particularly susceptible to bacteremia and meningitis, ophthalmitis and arthritis. Some of the important infectious causes of arthritis are as follows.

Calves

- Nonspecific joint-ill from omophalophlebitis associated with...
Some cases of ephemeral fever have a sterile arthritis
- BVD virus in young bulls, rarely
- Idiopathic septic arthritis in dairy heifers. The etiology is unknown
- Septic arthritis of the proximal interphalangeal (pastern) joint in cattle due to perforating wounds. A. pyogenes is the most common cause in cattle.

PATHOGENESIS
In infectious arthritis that is hematogenous in origin there is usually a synovitis initially, followed by changes in the articular cartilages and sometimes bone. With almost any systemic infection there may be localization of the infectious agent in the synovial membrane and joint cavity. The synovial membrane is inflamed and edematous, and there are varying degrees of villous hypertrophy and deposition of fibrin. Bacteria colonize in synovial membranes, which makes treatment difficult. The synovitis causes dispersion of the joint capsule with fluid and the joint is painful and warm. Successful treatment and elimination of infection at this early stage of synovitis will minimize changes in articular cartilage and bone and healing will result. A progressive infectious synovitis commonly results in pannus formation between articular surfaces with erosion of articular cartilage, infection of subchondral bone and osteomyelitis. In the chronic stages there is extensive granulation tissue formation, chronic synovitis and degenerative joint disease with osteophyte formation, and ankylosis is possible. Depending on the organism, the arthritis may be septic or serofibrinous. Suppurative arthritis is particularly destructive of cartilage and bone and commonly there is rupture of the joint capsule. In foals with septic arthritis there may be a concurrent polyarthritic, usually in either the epiphysis and/or the metaphysis of the long bones.

Experimental infectious arthritis in calves
Septic arthritis induced by E. coli is a reliable and reproducible model of infectious arthritis in laboratory animals, horses and calves. The inoculation of E. coli into the tarsal joint of newborn colostrum-fed calves resulted in septic arthritis in all calves. Clinical signs of septic arthritis appeared on day 2 after infection and persisted until day for all calves. E. coli was cultured from synovial fluid on day 2 for one calf and until day 4 for five other calves. Polymerase chain reaction (PCR) for E. coli was positive in the synovial fluid of all calves. Synovial fluid neutrophil and white blood cell counts were increased on days 2–4. All bacterial cultures were negative on day 8, although clinicopathological signs of inflammation persisted until day 20. Rapid recovery occurred within 1 week when an appropriate treatment was begun early in the course of the disease.
Foals with septicemia

Septicemic foals may develop infectious arthritis and a concurrent polyosteomyelitis because of the patency of transphyseal vessels in the newborn foal; this allows spread of infection across the physes with the development of lesions in the metaphysis, epiphysis and adjacent to the articular cartilage. The syndrome is classified according to the location of the lesions:

- A foal with S-type septic arthritis–osteomyelitis has synovitis without macroscopic evidence of osteomyelitis.
- Foals with E-type osteomyelitis have osteomyelitis of the epiphysis at the subchondral bone-cartilage junction.
- Those with P-type have osteomyelitis directly adjacent to the physis.
- The same joint may have a single type or any combination of types but most foals with the S-type have concurrent bone lesions.

Horses

Septic arthritis has been reproduced experimentally in horses and the sequential synovial fluid changes monitored. Following intra-articular inoculation of *S. aureus*, clinical signs are evident as early as 8 hours after infection. A high and persistent neutrophilia is one of the earliest and most accurate diagnostic abnormalities. The total white blood cell count rises within 12-24 hours to a mean value of 100 x 10^9/L. Total protein also increases. Synovial fluid acidosis also occurs in infectious arthritis, which may interfere with the antibacterial activity of some antimicrobials. In experimental arthritis, the synovial pH declined from a mean value of 7.43 to 7.12. Bacteria could be recovered from intra-articular fluid in 55% of the joints sampled.

Infectious arthritis may occur following traumatic injury to a joint but the pathogenesis is obscure. Traumatic injury of the joint capsule resulting in edema and inflammation may allow latent organisms to localize, proliferate and initiate an arthritis.

**CLINICAL FINDINGS**

Inflammation of the synovial membrane causes pain and lameness in the affected limb, sometimes to the point that the animal will not put it to the ground. Pain and heat are usually detectable on palpation and passive movement of the joint is resisted. The joint may be swollen but the degree will depend on the type of infection. Pyogenic bacteria cause the greatest degree of swelling and may result in rupture of the joint capsule. Some enlargement of the epiphysis is usual and this may be the only enlargement in nonpyogenic infections, particularly that associated with *E. insidiosa*.

Fever, inappetence to anorexia, endotoxemia, loss of body weight and discomfort may occur in animals with only one severely affected joint or when several joints are less severely affected.

In many of the neonatal infections there will also be an accompanying omphalophlebitis and evidence of lesions in other organs, particularly the liver, endocardium and meninges. Arthritis in older animals may also be accompanied by signs of inflammation of the serous membranes and endocardium when the infection is the result of hematogenous localization.

The joints most commonly involved are the hock, stifle and knee but infection is the result of hematogenous spread of infection across the physes with the development of lesions in the metaphysis, epiphysis and adjacent to the articular cartilage. The syndrome is classified according to the location of the lesions:

- A foal with S-type septic arthritis–osteomyelitis has synovitis without macroscopic evidence of osteomyelitis.
- Foals with E-type osteomyelitis have osteomyelitis of the epiphysis at the subchondral bone-cartilage junction.
- Those with P-type have osteomyelitis directly adjacent to the physis.
- The same joint may have a single type or any combination of types but most foals with the S-type have concurrent bone lesions.

**CLINICAL PATHOLOGY**

**Arthrocentesis**

Aspiration of joint fluid for culture and analysis is necessary for a definitive diagnosis. Careful disinfection of the skin and the use of sterile equipment is essential to avoid the introduction of further infection.

**Analysis of joint fluid**

Total and differential cell count, total protein concentration and specific gravity are determined.

In infectious arthritis the volume of joint fluid is increased and the total leukocyte count is increased, with a high percentage (80-90%) of neutrophils. The severity of infectious arthritis may be manifested systemically by a leukocytosis with a marked regenerative left shift. In degenerative joint disease, the volume may be normal or only slightly increased and the total and differential leukocyte count may be within the normal range. In traumatic arthritis there may be a marked increase in the number of erythrocytes. Special biochemical examinations of joint fluid are available that measure for viscosity, strength of the mucin clot and concentrations of certain enzymes. Laboratory findings in examination of the joint fluid are summarized in Table 13.2. The synovial fluid analysis of 130 cases in cattle compared the characteristics of animals with infectious and noninfectious arthritis.

**Culture of joint fluid**

Joint fluid must be cultured for aerobic and anaerobic bacteria and on specific media when *Mycoplasma* sp. is suspected. It is often difficult to isolate bacteria from purulent synovial fluid. The rates of recovery of organisms vary from 40-75%. In one study of suspected infectious arthritis in 64 horses admitted to a veterinary teaching hospital over a period of 8.5 years, positive cultures were obtained from 55% of the joints sampled. The most common organisms were *S. aureus, E. coli* and *Pseudomonas aeruginosa*, accounting for more than half the isolates obtained.

There is no single test that is reliable for the diagnosis of septic arthritis. Failure to isolate organisms on culture does not exclude the a bacterial cause, and
organisms are often not observed in synovial fluid smears. Poor collection, storage and laboratory techniques, prior administration of antibiotics or partial success of the immune system in containing the infection may explain the failure to detect organisms. Arthrocentesis should be done before antibiotics are given and a blood culture bottle should be inoculated immediately, a Gram stain made and culture for anaerobes included. Positive cultures from synovial fluid can be expected in only about 65% of cases.

A biopsy sample of synovial membrane may be more reliable than synovial fluid for culture but there is little evidence based on comparative evaluations to support such a claim. PCR has been examined in in-vitro studies to detect selected bacterial species in joint fluid compared with microbial culture. The benefits would include rapid and accurate diagnosis infectious arthritis, ability to detect bacteria in synovial fluid in the presence of antimicrobial drugs and diagnosis of infectious arthritis when culture results are inconclusive. However, initial studies found no difference between microbial culture and PCR analyses.

**Serology of joint fluid**

Serological tests may be of value in determining the presence of specific infections with *Mycobacterium mycobides*, *Salmonella* spp., *Brucella* spp., and *E. insidiosa*. Radiographic examination may aid in the detection of joint lesions and can be used to differentiate between inflammatory and degenerative changes. In foals with arthritis and suspected osteomyelitis there may be radiographic evidence of osteolysis of the metaphysis or epiphysis.

**Radiography**

Radiography of the affected joint will often reveal the nature and severity of the lesions. Typical radiographic findings of septic arthritis include osteolytic lesions of the articular cartilage, increased width of intra-articular joint space, and soft tissue swelling. Osteomyelitic changes are seen in some cases. Because radiographic changes usually appear after 2-3 weeks when destruction of subchondral bone has become extensive, it may be necessary to take a series of radiographs several days apart before lesions are detectable.

**Ultrasoundography**

Arthrosography is an effective, fast and noninvasive complement to traditional diagnostic techniques for comprehensive evaluation of the pathology of joints of cattle. Distension of the joint cavities can be imaged; assessing echogenicity, acoustic enhancement and ultrasonographic character of the exudate correlates well with findings by arthrocentesis, arthroscopy or at necropsy. Joint effusion, which is the earliest indication of septic arthritis, can usually be detected with ultrasound by an experienced operator in the early stages. The synovial membrane, synovial fluid, ligaments, tendons and periarticular soft tissue, only inadequately imaged by radiography, can be imaged with ultrasonography. In advanced septic arthritis, ultrasonography provides accurate information on the location of the soft-tissue swelling, the extent and character of the joint effusion and involvement of concurrent periarticular synovial cavities.

**Arthroscopy**

Endoscopy is now used widely to define joint abnormalities more clearly and to gain access to the joint cavity as an aid in the treatment of septic arthritis.

**Necropsy findings**

The nature of the lesions varies with the causative organism. The synovial membrane is thickened and roughened and there is inflammation and erosion of the articular cartilage. There is usually an increase in the amount of synovial fluid present, varying from a thin, clear, serous, brownish fluid through a thicker, serofibrinous fluid to pus. There may be some inflammation of the periarticular tissues in acute cases and proliferation of the synovial membrane in chronic cases. In the latter, plaques of inspissated necrotic material and fibrin may be floating free in the synovial fluid. Infectious arthritis due to *A. pyogenes* is characterized by extensive erosion and destruction of articular cartilage and extensive suppuration. There may be a primary omphalophlebitis in newborn animals and metastatic abscesses may be present in other organs.

**Differential diagnosis**

- **Infectious arthritis** is characterized clinically by swollen joints which are painful and warm to touch, and lameness of varying degrees of severity. The volume of joint fluid is usually markedly increased and the leukocyte count is increased with a high percentage of neutrophils. In the early stages of synovitis and in chronic nonsuppurative arthritis, the joint may not be visibly enlarged and careful examination by palpation may be necessary to reveal abnormalities of the joint capsule. Lameness is common, however, even though only slight in some cases, and should arouse suspicion of the possibility of arthritis.
  - The diseases of the musculoskeletal system that cause lameness and stiffness of gait include:
    - Degenerative joint disease
    - Osteodystrophy and epiphysitis
    - Osteomyelitis
    - Degenerative myopathy
    - Myositis
    - Traumatic injuries of tendons and ligaments
    - Diseases of the nervous system, especially the peripheral nerves and spinal cord, may be confused with arthritis unless the joints are examined carefully.
    - Some severe cases of polyarthritis may cause recumbency that may be erroneously attributed to the nervous system.

**Degenerative joint disease** is characterized by an insidious onset of moderate lameness and stiffness of gait that becomes progressively worse over several weeks. The joint capsule is usually not grossly enlarged and not painful, and there is usually no systemic reaction. The total leukocyte count in the joint fluid is only slightly increased and the differential count may be normal. Chronic arthritis is often difficult to differentiate clinically from degenerative joint disease. Chronic arthritis is more common in young animals than in older animals such as rapidly growing yearling bulls, adult bulls, aged dairy cows and horses, in which degenerative arthropathy is most common. A sudden onset of acute lameness and marked swelling of a joint with severe pain suggests an infectious arthritis or traumatic injury to the joint. Marked swelling of several joints suggests infectious polyarthritis.

**Osteodystrophy** is characterized by:

- Lameness and stiffness of gait
- Usually an absence of joint capsule abnormalities
- Enlargements and deformities of the long bones in growing animals
- A number of animals may be affected at about the same time.

Radiography may reveal the abnormal bones and the nutritional history may explain the cause.

**Degenerative myopathy** causes acute lameness, a stiff and trembling gait, often leading to recumbency and absence of joint or bone involvement.

**Traumatic sprains of tendons or ligaments** and fractures of the epiphyses may cause lameness and local pain, and, when they involve periarticular tissues, may be difficult to differentiate from arthritis.

**Arthritis is never present at birth** and apparent fixation of the joints should arouse suspicion of a congenital anomaly. The differentiation between arthritis and diseases of the peripheral nerves or spinal cord, both of which can cause lameness and/or recumbency, may be difficult if the arthritis is not clinically obvious. Diseases of the peripheral nerves cause lameness due to flaccid paralysis and neurogenic atrophy. Lesions of the spinal cord usually result in weakness of the hindlimbs, weak or absent withdrawal reflexes and loss of skin sensation.
TREATMENT

Parenteral antimicrobials

Acute septic arthritis should be treated as an emergency to avoid irreversible changes in the joint. The conservative approach is the use of antimicrobials given parenterally daily for several days and up to a few weeks in some cases. The selection of the drug of choice will depend on the suspected cause of the arthritis. The antimicrobial sensitivities of bacterial isolates from horses with septic arthritis/synovitis or osteomyelitis after fracture repair vary widely. A combination of cephalosporin and amikacin is recommended before culture and sensitivity results are available.

The antimicrobials that perfuse into the joint in therapeutic concentrations include the natural and synthetic penicillins, tetracyclines, trimethoprim-potentiated sulfonamides, neomycin, gentamicin, and kanamycin.

Clexacin, methicillin, or penicillin have been used successfully for the treatment of staphylococcal septic arthritis in the horse.

Amphotericin B given intravenously daily for up to 30 days combined with joint drainage has been used for the treatment of Candida sp. arthritis in the horse.

The relative efficacies of antimicrobials administered parenterally versus by intra-articular injections has been uncertain. Trimethoprim–sulfadiazine, given to calves parenterally, results in therapeutic concentrations of the drug in the synovial fluid of calves and penetrability was not enhanced nor restricted by experimental joint inflammation. Oxytetracyclines and penicillin given parenterally readily penetrate the synovial membrane of both normal neonatal calves and those with experimental arthritis. Since peak synovial fluid levels of oxytetracycline and penicillin exceeded the minimum inhibitory concentrations for organisms such as A. pyogenes, the use of parenteral antimicrobials for the treatment of infectious arthritis in calves is appropriate.

Ceftiofur at 1 mg/kg BW intravenously every 12 hours for 20 days, along with joint lavage, was successful in treating experimental septic arthritis associated with E. coli. The duration of antibiotic therapy is empirical; 3 weeks is recommended. Cephapirin administered parenterally to normal calves or those with arthritis resulted in synovial fluid levels approximately 30% of serum levels. The use of ampicillin trihydrate in calves with supplicative arthritis, at a dose of 10 mg/kg BW intramuscularly, resulted in a peak serum concentration of 2.5 μg/mL, 2 hours after injection; the highest concentration in normal synovial fluid was 3.5 μg/mL at 4 hours and the highest concentration in suppurative synovial fluid was 2.7 μg/mL at 2 hours.

Marbofloxacin at 4 mg/kg BW intramuscularly daily for 10 days was effective for the treatment of infectious arthritis in calves. Amoxicillin at 40 mg/kg BW intravenously is effective for the treatment of infectious joint disease in horses.

The administration of trimethoprim–sulfadiazine at 30 mg/kg BW orally once daily to horses with experimentally induced S. aureus arthritis was ineffective in maintaining adequate levels of both drugs in infected synovial fluid. The use of the same drug at 30 mg/kg BW orally given every 12 hours was effective in maintaining therapeutic concentrations of both drugs in the serum and in the joint fluid.

In piglets at 2 weeks of age, streptococcal arthritis is most likely and it will respond quickly to penicillin given parenterally. Likewise, acute arthritis associated with erysipelas in pigs will respond beneficially if treated early before there is pannus formation.

Synovitis due to Histophilus somni infection responds quickly to systemic treatment. However, in other specific types of infectious arthritis the response is poor and recovery, if it does occur, requires several days or a week. Mycoplasmal arthritis in cattle is relatively non-responsive to treatment and affected cattle may be lame for up to several weeks before improvement occurs and complete recovery may not occur. Chronic arthritis due to infection of pigs with E. insidiosa will commonly develop into a rheumatoid-like arthritis and be refractory to treatment.

Failure to respond to conservative therapy has been attributed to:

- Inadequate concentrations of antimicrobials achieved in the joint cavity
- Presence of excessive amounts of exudate and fibrin in the joint making the infectious agent inaccessible to the antimicrobial
- Drug-resistant infections
- The development of rheumatoid-like arthritis, which is chronic and progressive

It is often not possible to determine which situation is responsible.

If conservative treatment is not providing sufficient improvement and the value of the animal warrants extended therapy, a joint sample should be obtained for culture and sensitivity. The most suitable antimicrobial may then be given parenterally and/or by intra-articular injection. Strict asepsis is necessary to avoid introduction of further infection.

Intra-articular antimicrobials

The combined intra-articular and intravenous administration of gentamicin to normal horses can result in concentrations 10–100 times greater than after intravenous administration alone. In addition, gentamicin concentration in synovial fluid remained above the minimum inhibitory concentration for many common equine bacterial pathogens for at least 24 hours after treatment. The intra-articular administration of gentamicin is advantageous for the treatment of infectious arthritis in animals in which the systemic administration of the drug may be contraindicated, especially in the presence of impaired renal function or endotoxemia. Continuous infusion of gentamicin into the tarsocrural joint of horses for 5 days is an acceptable method of treating septic arthritis.

Antimicrobial-impregnated polymethylmethacrylate beads have been used for the treatment of orthopedic infections involving bone, synovial structures and other soft tissues. The antimicrobials diffuse from the beads in a bimodal fashion. There is a rapid release of 5–45% of the total amount of antimicrobial within the first 24 hours after implantation and then a sustained elution that persists for weeks to months, depending on the antimicrobial used. For effective diffusion, the antimicrobials must be water-soluble, heat-stable and available in powder form. Aminoglycosides and the cephalosporins have been incorporated most completely into the beads.

Regional limb perfusion with antimicrobials has been used for the treatment of experimentally induced septic arthritis. The antimicrobial is infused under pressure to a selected region of the limbs through the venous system. The concentration of the antimicrobial in the septic synovial fluid will usually exceed those obtained by intravenous administration. If the infusion is performed in the control of sepsis, there is insufficient data available to evaluate the procedure in naturally occurring cases. Therapeutic concentrations of cefazolin are achieved in the synovial fluid of clinically normal cows when injected intravenously distally to a tourniquet and the technique could be used as an alternative to systemic administration of antimicrobials to provide adequate concentrations in a joint cavity.

Lavage of joint

Drainage of the affected joint and through-and-through lavage of the joint is also desirable along with the systemic administration of antimicrobials. Aspiration and distension–irrigation of the joint cavity using polyionic electrolyte solutions buffered to pH 7.4 is recommended.
irrigation removes exudates and lysozymes that destroy articular cartilage. A through-and-through lavage system may also be used with drainage tubes. General or local anesthesia should be provided. The distended joint is identified by palpation, the hair is clipped short and the skin is prepared with appropriate surgical disinfection. A 2 cm 16-gauge needle is inserted into the joint cavity, avoiding direct contact with the bones of the joint. A second needle is inserted into the joint as far as possible from the first needle to cause any fluid perfused into the joint to pass through as much of the joint cavity as possible. 0.5–1 L of Ringer’s solution warmed to 37°C is flushed through the joint using a hand-pumped pressure bag to keep a steady fluid flow into the joint.6

Arthroscopy
Arthroscopy provides excellent visualization of most parts of an affected joint and can be used to access the joint for the treatment of septic arthritis.5 The endoscope can be used to explore and debride the affected joint during the same intervention. Purulent exudate can be removed and necrotic areas within the synovial membrane can be debrided.

Surgical drainage and arthroscopy
Failure to respond to parenteral and intra-articular medication may require surgical opening of the joint capsule, careful debridement and excision of synovium and infected cartilage and bone. This may be followed by daily irrigation of the joint cavity with antimicrobials and saline. A lavage system can be established and the joint cavity infused with an antimicrobial and saline daily for several days.33 Arthroscopy with lavage was more effective in eliminating joint infections by providing better drainage than arthroscopy, synovectomy and lavage. However, with arthroscopy the risk of ascending bacterial contamination is greater and the major difficulty is to eliminate the infection from the joint and incision site.33 Infected sequestra and osteomyelitis of subchondral bone will prevent proper healing. Curettage of septic phyleal lesions in foals may be necessary.

Open drainage and intra-articular and parenteral antimicrobials has been used to treat persistent or severe septic arthritis/tenosynovitis. While joint lavage through needles is still effective in many horses with acute infectious arthritis or tenosynovitis, in those with chronic or recurring septic arthritis, open drainage is indicated to remove the inflammatory exudate from the synovial space. Infected synovial structures are drained through a small (3 cm) arthrotomy incision left open and protected by a sterile bandage. Joint lavage using antimicrobials is done daily and parenteral antimicrobials are given intensively.

Septic pedal arthritis in cattle may be treated successfully by the creation of a drainage tract to promote adequate drainage. In cattle with septic arthritis of the digit, placement of a wooden block under the unaffected digit decreases weight-bearing on the affected digit and provides for earlier, less painful amputation.52

Arthrodosis or artificial ankylosis
Surgical arthrodesis can be used for the treatment of chronic septic arthritis in horses and calves.26,27

Septic arthritis of the distal interphalangeal joint is a common complication of diseases of the feet of cattle. Facilitated ankylosis of the joint is a satisfactory alternative to amputation of the affected digit in valuable breeding animals.28 In a series of 12 cases of septic arthritis of the distal interphalangeal joint treated by use of facilitated ankylosis, the success rate was 100%.

Physical therapy
The local application of heat, by hot fomentations or other physical means, is laborious but, if practiced frequently and vigorously, will reduce the pain and local swelling. Analgesics are recommended if there is prolonged recumbency. Persistent recumbency is one of the problems in the treatment of arthritis, particularly in foals. The animal spends little time feeding or sucking and loses much condition. Compression necrosis over bony prominences is a common complication and requires vigorous preventive measures.

Anti-inflammatory agents
NSAIDs are used parenterally to decrease the inflammatory response and to provide analgesia. In experimental synovitis in the horse, similar to septic arthritis, phenylbutazone was more effective than ketoprofen in reducing lameness, joint temperature, synovial fluid volume and synovial fluid prostaglandin.29

Prognosis for survival and athletic use in horses with septic arthritis
The factors affecting the prognosis for survival and athletic use in 93 foals treated for septic arthritis have been examined.12 The femoropatellar and tarsocrural joints were most commonly affected. Osteomyelitis or degenerative joint disease were detected in 59% of the foals. Failure of transfer of passive immunity, pneumonia and enteritis were common. Treatment consisted of lavage, lavage and arthroscopic debridement with or without partial synovectomy, or lavage and arthroscopy to debride infected bone and parenteral antibiotics. Seventy-five foals survived and were discharged from hospital, and approximately one-third raced. Isolation of Salmonella from synovial fluid was associated with an unfavorable prognosis for survival, and multisystemic disease was associated with an unfavorable prognosis for survival and ability to race.

The key to successful outcome for septic arthritis is rapid diagnosis and initiation of treatment.

In a series of 507 horses treated for joint disease at one equine hospital during a period of 7 years, the risk factors affecting discharge from the hospital, of ever being sound, or of being alive after a 3-month followup were examined,20 58% of foals, 78% of yearlings and 94% of racing adults were discharged. Foals with a less severe lameness, duration of less than 1 day and infectious arthritis had increased odds of discharge.

CONTROL
The control of infectious arthritis is of major importance in newborn farm animals. The early ingestion of adequate quantities of good-quality colostrum and a clean environment for the neonate are necessary. The prophylactic use of antimicrobials may be considered to reduce incidence. Some of the infectious arthritis associated with specific diseases can be controlled through immunization programs. For example, vaccination of piglets at 6–8 weeks of age will provide protection against both the septicemic and arthritic forms of erysipelas.

REVIEW LITERATURE

REFERENCES
25:788.
Defects of the musculoskeletal system are among the most common congenital abnormalities in farm animals. In cattle 476 such defects are listed. Many of them are lethal, and most of the remainder are life-threatening because of interference with grazing or the prehension of food. Many of them occur in combinations so that single defects are uncommon. For example, most axial skeletal defects and cleft palates occur in calves that already have arthrogryposis.

Because of the very large volume of literature involved it is not possible to deal with all the recorded defects here, and the text is limited to those defects that are thought to be of general importance. Whether or not they are inherited or have an environmental cause is often not known so that an etiological classification is not very effective. Nor is an anatomical or pathological classification, so we are reduced to a classification based on abnormal function.

### FIXATION OF JOINTS

Because arthrogryposis, which has been used to convey the description of joint fixation, strictly means fixation in flexion, the term congenital articular rigidity has been introduced. The immobilization of the joint may be due to lack of extensibility of muscles, tendons, ligaments or other tissues around the joint, or to deformity of articular surfaces, or theoretically to fusion between the bones at the articular surface. Muscle contracture, which is the principal cause of joint fixation, has been produced experimentally, and occurs naturally, as a result of primary muscle atrophy or of atrophy resulting from denervation. Articular surface deformity is usually associated with gross deformity of the limb bones and is usually identifiable but the principal problem in the diagnosis of congenital articular rigidity is to determine what the pathogenesis might have been and, beyond that, what was the specific cause.

### Congenital fixation of joints can be caused by some well known entities, as follows.

#### Cattle
- **Hereditary congenital articular rigidity (HCAR) with cleft palate in Charolais calves**
- **HCAR with normal palates in Friesians, Danish Red, Swedish Red, Shorthorns**
- **Inherited arthrogryposis**
- **Inherited multiple tendon contracture**
- **Inherited multiple ankylosis of Holstein-Friesian cattle.**

### Environmentally induced congenital articular rigidity caused by:
- **Intrauterine infection with Akabane virus**
- **Infection of lups**
- **Infection of Astragalus and Oxytrops spp. (locoweeds)**
- **Sorghum, Johnson grass, Sudan grass**
- **Diabetic deficiency of manganese.**

#### Sheep and goats
- **Inherited congenital articular rigidity in Merino sheep**
- **Infection with Akabane virus**
- **Poisonous plants as for cattle**
- **Poisoning with parbendazole and cambendazole.**

#### Piglets
- **Inherited congenital articular rigidity**
- **Nutritional deficiency of vitamin A**
- **Poisonous plants, hemlock (Conium maculatum), Prunus serotina, Jonson weeds (Datura stramonium), tobacco wastes.**

#### Foals
- **'Contracted' foals** having congenital axial and appendicular contractures of joints in the us, cause unknown, not thought to be inherited. Deformities include torticollis, scoliosis, thinning of ventral abdominal wall, sometimes accompanied by eventration, asymmetry of the skull, flexion contracture in distal limb joints
- **Congenital articular rigidity** also occurs in foals from mares fed on hybrid Sudan grass pastures
- **Sporadic cases of congenital joint deformity** occur in foals and calves. They are manifested usually by excessive flexion of the metacarpophalangeal joints causing affected animals to 'knuckle at' the fetlocks and sometimes walk on the anterior aspect of the pastern. A similar defect occurs in the hindlegs. Many mild cases recover spontaneously but surgical treatment may be required in badly affected animals. The cause in these sporadic cases in unknown and necropsy examination fails to reveal lesions other than excessive flexion of the joints caused by shortening of the flexor tendons. Rarely such fixations are associated with spina bifida or absence of ventral horn cells of the spinal cord.

### HYPERMOBILITY OF JOINTS

This is recorded as an inherited defect in Jersey cattle. Affected animals are unable to rise or stand because of the lack of fixation of limb joints. The joints and limbs are usually all affected simultaneously and are so flexible that the limbs can be tied in knots. Causes include:
- **Inherited joint hypermobility in Jersey cattle**
- **Hereditary in Holstein-Friesian cattle, which also have pink teeth due to absence of enamel.**
- **In inherited congenital defects of collagen formation including dermatosparaxsis, hyperelastosis cutis and Ehlers-Danlos syndrome in cattle.**
- **Sporadically in newborn animals.**

### WEAKNESS OF SKELETAL MUSCLES

A number of sporadic myopathies are recorded in cattle and sheep. Causes have not been determined in most of them. Splayleg in pigs has been well described and occurs in most countries.

### CONGENITAL HYPERPLASIA OF MYOFIBER

There is only one identified state; it is the inherited form of doppelender, double muscling or culard of cattle, described in Chapter 35. The principal cause of the bulging muscles is an increase in the number of myofibers in the muscle.

### OBVIOUS ABSENCE OR DEFORMITY OF SPECIFIC PARTS OF THE MUSCULOSKELETAL SYSTEM

A number of these defects are known to be inherited and are dealt with in Chapter 34. They include:
- **Achondroplastic dwarfism, inherited miniature calves, bulldog calves**
- **Umbilical, scrotal hernia, cryptorchidism.**
- **Tail deformity (kinking), tailllessness**
- **Reduced phalanges, including hemimelia (individual bones missing), amputates (entire limbs missing), vesimal limbs (parts present but limbs miniaturized).**

Amputates in outbreak form are recorded in cattle and produced experimentally by irradiation injury of sows, cows and ewes during early pregnancy.
Congenital defects of muscles, bones and joints

- Inherited arachnomyelia (spidery limbs) of calves
- Congenital thickleg of pigs, osteopetrosis of calves, muscular hypertrophy of calves
- Cyclopian deformity. Inherited form associated with prolonged gestation. Toxic form associated with ingestion of *Veratrum californicum*
- Displaced molar teeth, mandibular prognathism. Agnathia in lambs takes a variety of forms, including complete absence of lower jaw and tongue.
The major functions of the skin are:

- To maintain a normal body temperature
- To maintain a normal fluid and electrolyte balance within the animal
- To act as a sensory organ perceiving those features of the environment which are important to the subject's survival.

In general these functions are not greatly impeded by most diseases of the skin of large animals, with the exceptions of failure of the sweating mechanism, which does seriously interfere with body temperature regulation, and severe burns or other skin trauma, which may cause fatal fluid and electrolyte loss.

The major effects of skin diseases in large animals are esthetic and economic. For transport and appearance in exhibitions' especially in other sovereign states, there may be interference with prehension. There is loss of the economic coat and the sales value and acceptability of animals for transport and appearance in exhibitions, especially in other sovereign states, is greatly reduced.

Primary/secondary lesions

Diseases of the skin may be primary or secondary in origin. In primary skin disease the lesions are restricted initially to the skin although they may subsequently spread from the skin to involve other organs. On the other hand, cutaneous lesions may be secondary to disease originating in other organs. Differentiation between primary and secondary skin diseases should be attempted by seeking evidence that organs other than the skin are affected. If there is such evidence produced during a complete clinical examination of the patient, it is reasonable to assume that the disease is primary. Even if involvement of other organs is diagnosed it is still necessary to determine whether the involvement constitutes the primary state or whether it has developed secondarily to the skin disease. This decision can be based on the chronology of the signs, elicited by careful history-taking, and a detailed knowledge of the individual diseases likely to be encountered.

When a careful clinical examination has been made and an accurate history taken it is then necessary to make a careful examination of the skin itself, using the proper technique of examination, especially (and essentially) histopathological examination of a biopsy specimen. It is then possible to determine the basic defect, whether it be inflammatory, degenerative or dysfunctional, and thus to define the type of lesion present.

The purpose of this chapter is to describe the basic skin lesions so that the differential diagnosis, up to the point of defining the type and nature of the lesion, the pathoanatomical diagnosis, can be accomplished. A definitive etiological diagnosis requires further examination and is included in the discussion of the specific diseases in Part Two of this book.
